It is rumored that Sir Thomas Crawford, K.C.B., will be the last chief of the Army Medical Department. This latter will be placed under a Board consisting of two non-medical officers and one medical ditto. It is also stated that some concession will be made to the Army Medical De-

partment in reference to their grievance that they have been lately deprived of relative rank. The majority of the medical officers of the Army are in favor of having military titles, as is the case with the armies of Russia, the United States, etc. So far as personal danger is concerned the Army medical men have of late suffered more than any other branch of the service. It is thought that there is no good reason why a medical officer who is obliged to be in front of the battle and compelled to fight also, should not be called by a purely military title. In the olden days of the British Army it was usual for medical officers to hold commissions as combatants also.

"Sixteen Years of the Metropolitan Hospital Sunday Fund" was the part title of a lecture recently delivered by Sir Sidney Waterlow at St. Bartholomew's Hospital, when the Lord Mayor presided. He said that last year £40,379 had been collected, making a grand total for the sixteen years of £513,962, including legacies. Of this less than teupence in the pound had been spent in salaries, collecting, distributing and advertising. In the division of the money, 4 per cent. was devoted to the purchase of surgical appliances, which were given away to the poor, then awards to hospitals were based on the average total expenditures of the three previous years, and each hospital was required to send a balance sheet and report for three years, with other details verifying receipts and expenditures. Sir Sidney said there were at present 2,031 beds in seventy-one metropolitan hospitals empty for lack of funds.

Bee-stings are now recommended as a somewhat heroic treatment for rheumatism. It is stated that an average of just 225.4 stings suffice to effect a cure in any one case. The introducer of the bee-sting treatment is evidently almost as ardent an entomological enthusiast as Sir John Lubbock, for he takes great pains to state that bee-stings are not nearly so dangerous as most people imagine, for he has, by way of demonstrating this proposition, given several healthy persons 150 stings apiece in the course of a single day without any ill consequences whatever. Acupuncture has in its day had its supporters, but what, if any, may be the advantages of apiopuncture must be left for time and experience to determine. Whether, however, there are any healthy persons in this country willing to receive in the cause of science some 150 stings *per diem*, or even any rheumatic patients who would like to be cured by 225½ stings, must be left for Dr. F. Tere, the introducer of the new remedy, to find out.

The active principle of gorse (*Ulex Europæa*) has been made the subject of special experiments, the alkaloid used being in the form of hydrobromate of ulexine. When it was applied to frogs this drug, at a certain dose, arrests all voluntary movements and reflexes, due to palsy of the motor

tract of the spinal cord and the motor nerve trunks. The muscles themselves gradually fail but, unless the dose has been very high, are not paralyzed. Respiration is affected and arrested by doses which are not large enough to produce much effect upon the voluntary muscles. The symptoms of this respiratory action come on with irregular breathing, which finally becomes more shallow until death ensues. When the hydrobromate of ulexine is given to one of the higher animals, it produces a rise of arterial pressure which lasts only for a short time, being followed by a fall. It is shown that the depressant action of the drug is its most important feature, for if large doses are used no primary rise, but a steady fall occurs. This fall is evidently due largely to a laming of the heart muscle by the direct action of the drug. The diuretic action of ulexine is very marked, being quite as great as that of caffeine. The opinion entertained is that the action of ulexine and its compounds upon the respiration is of so violent a character that it will be difficult, if not impossible, to make use of this agent in medicine. At any rate, it appears to be one of the most powerful alkaloids ever discovered, and requires the greatest care in manipulating it. Further experiments are now being carried out with the drug by experimenters who think it will eventually take its place as a very useful addition to the pharmacopeia of the future.

The British Dental Association will hold its annual meeting in Brighton on August 22, 23 and 24. The Association is doing much to educate the public on dental questions, and is uniting and consolidating the members of the dental profession. The meeting promises in every way to be a success.

The annual children's fête has recently been held at the Evelina Hospital for sick children. Through the generosity of various friends four large Christmas trees were provided. It may be mentioned that the hospital, of which Baron F. de Rothschild is President, has sixty cots permanently in use, and that in the course of a twelve-month some 500 children pass through the wards. Since the last Christmas fête the floors of all the wards have been relaid with teak according to the practice adopted in the principal general hospitals, and though the nurses past and present have borne the expense so far as one ward is concerned, an additional burden has been cast upon the institution.

The report having gained general currency that the use of saccharin is injurious, the following report has been published by Dr. Thomas Stevenson, official analyst of the Home Office: 1. Saccharin is quite innocuous when taken in quantities largely exceeding what would be taken in any ordinary dietary. 2. Saccharin does not interfere with or impede the digestive processes when taken in any practicable quantity. 3. His personal ex-

perience is that saccharin may be taken for an extended period without interfering with the digestive and other bodily functions, hence there is no reason to think that its continued use is in any way harmful.

It is reported from Paris that the Pasteur Institute is now complete, and the laboratory appliances of the great bacteriologist are now being transferred to the new and magnificently appointed building. G. O. M.

MISCELLANY.

DR. WM. G. AUSTIN has been recently appointed resident quarantine physician at Mississippi Station.

DR. HORACE STEVENS, of Cambridge, Mass., died on February 24. He was graduated from the Medical Department of the University of Vermont. He was born in New Hampshire in 1816.

DR. EMANUEL BRAILLER, a prominent physician of Chambersburg, Pa., died on February 6, aged 48 years. He was a member of the American Medical Association, and of the Pennsylvania State Medical Society.

INFECTIOUS DISEASES.—Scarlet fever has been prevailing in Bismarck, Dak., for some time, and all churches, schools, and places of amusement have been closed. Diphtheria has been prevalent in Mechanicsville, Iowa. An outbreak of smallpox has occurred at Carson, Neb. At Belvidere, Ill., the schools have been closed in consequence of the prevalence of measles, varicella, and scarlet fever.

THE AMERICAN ASSOCIATION FOR THE STUDY AND CURE OF INEBRIETY has appointed a committee on "Nostrums, Proprietary Medicines, and New Remedies." Dr. N. Roe Bradner, 514 So. Third St., Philadelphia, Pa., is chairman of the committee, and will be glad to hear from any one who has knowledge of nostrums containing opium, alcohol or other poison, or of the evil resulting from their sale. This Association, of which Dr. Joseph Parrish, of Burlington, N. J., is now President, was organized November 30, 1870, the late Willard Parker being the first President, and the first paper, on the "Pathological Influence of Alcohol," was contributed by N. S. Davis, M.D., of Chicago.

A SIMPLE TEST FOR BLOOD, and easy of application, is made by the addition of tincture of guaiac and ozonized ether to a weak solution of blood, when a bright blue color is produced. If a drop of blood be mixed with one-half ounce of distilled water, upon the addition of one or two drops of tincture of guaiac a cloudy precipitate of the resin appears, and the solution has a faint tint. If to this solution one drop of an ethereal solution of hydrogen peroxide is added, a blue tint appears, which, upon a few minutes' exposure, gradually deepens. This test is very valuable for minute quantities of blood, and Dr. Day, of Geelong, succeeded in obtaining sixty impressions from a stain upon cloth where the microscope failed to show any blood.—*Coll. and Clinical Record.*

AT THE COMMENCEMENT EXERCISES of the Meharry Medical Department and the Dental Department of Central Tennessee College, held on February 21, the degree of M.D. was conferred upon 14, and the degree of D.D.S. upon 6 candidates. The Dental Department of this College is the only dental school for Negroes in this country, and the Meharry school is one of the two medical schools for Negroes.

DR. HENRY H. LANGWORTHY, of Rochester, N. Y., died at his residence in that city on February 5. He was graduated from the Geneva Medical College in 1848. He was a prominent member of the New York State Medical Society.

MEDICAL GRADUATES.—At the annual Commencement of Rush Medical College, Chicago, held on February 19, 127 candidates were graduated. At the Commencement of the College of Physicians and Surgeons, of Chicago, held on February 26, 48 candidates were graduated.

J. H. PURDY, M.D., formerly of Seneca Falls, N. Y., died recently, of yellow fever, at Panama, where he had gone to practice his profession. He was a graduate of Bellevue Hospital Medical College, in 1869.

THE FIFTH ANNUAL MEETING of the Fifth District Branch of the New York State Medical Association will be held in Brooklyn, on Tuesday, May 28, 1889. All Fellows are invited to present papers, communications, relation of cases and specimens at the meeting. All written communications presented will be published under the direction of the Executive Committee.

WM. T. LUSK, M.D., President.

E. H. SQUIBB, M.D., Sec'y, P. O. Box 94, Brooklyn.

INGLUVIN IN THE VOMITING OF PREGNANCY.—Dr. Popp reports considerable success with ingluvin in the vomiting of pregnancy. Having a very obstinate case, upon which he had exhausted all other resources, he administered three times daily, one-half hour before meal-time, 8 grains of ingluvin, and immediately afterward 2 tablespoonfuls of 1 per cent. hydrochloric acid solution. An improvement was observed after a few doses had been taken, and cure was effected after the treatment had been continued for three weeks.—*Deutsche med. Wochenschrift*, January 17, 1889.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from February 23, 1889, to March 1, 1889.

Lieut.-Col. James C. McKee, Surgeon U. S. Army, is granted leave of absence for two months, by direction of the Secretary of War. Par. 13, S. O. 44, A. G. O., Washington, February 24, 1889.

Major Charles R. Greenleaf, Surgeon, will proceed from this city as early as practicable to Newport Bks., Ky., to examine and report upon a proposed change in the location of the post hospital at the new barracks now in process of construction near that post; thence to Columbus Bks., O., to examine and report upon the necessity for an addition to the hospital at that post. Par. 16, S. O. 43, A. G. O., Washington, February 20, 1889.

Capt. Charles B. Byrne, Asst. Surgeon, granted leave of absence for twenty-one days. S. O. 44, Hdqrs. Div. of the Atlantic, Governor's Island, New York City, February 21, 1889.

By direction of the Secretary of War, Capt. William O. Owen, Jr., Asst. Surgeon, is relieved from duty at Ft. Leavenworth, Kan., and will report in person to the commanding officer, Ft. Gibson, Indian Ter., for duty at that post, relieving Capt. C. N. B. Macauley, Asst. Surgeon, who, on being so relieved, will report in person to the commanding officer, Ft. Leavenworth, Kan., for duty at that post. Par. 3, S. O. 48, A. G. O., February 21, 1889.

ORIGINAL ARTICLES.

DOUBLE UTERUS AND VAGINA.

BY L. H. DUNNING, M.D.,
OF SOUTH BEND, IND.

In a previous paper the writer presented a summary of facts and conclusions arrived at after studying the histories of 97 cases of malformation of the uterus and vagina due to defective development of the ducts of Müller. He has since collected and tabulated the histories of 224 more cases, all obtained from what he believes to be reliable sources. These, together with the 97 reported in the former article, comprise all the cases, except a very few not at the time obtainable, to be found in the library of the Surgeon-General's office at Washington, and the writer thinks will furnish us data for arriving at correct conclusions.

The tables were originally designed for publication, but are found too voluminous; but as they contain many points of interest to the general practitioner, and some of them are at variance with statements made by writers of acknowledged authority, the writer has thought a summary of some of the facts obtained might be of value to the profession. The tables just referred to are made up from reports of 224 cases and are four in number. Number 1 is a record of 100 cases of congenital malformation of the uterus in which pregnancy occurred. In twenty-nine of the cases the vagina was double.

Table No. 2 records 20 cases in which pregnancy occurred in women having double vaginae while the uteri were of normal development.

Table No. 3 relates to malformations of the uterus where pregnancy never occurred. There are 90 cases recorded thirty-five of which are associated with double vagina. Lastly table No. 4 is a record of 12 cases of non-pregnant normal uteri each one associated with a double vagina. In this paper, chiefly for the writers convenience, he will follow the line of study indicated by these tables.

The term double uterus, as in the former paper, is used to include all congenital malformations of the uterus described by Todd¹ as uterus

bipartitus, uterus unicornis, uterus bicornis, and uterus bilocularis. By accepting the anatomical description of this author all the various subdivisions may be easily included as these of our general classes.

The comprehensive term, double vagina, is intended to include all vaginae divided into two parts by an antero-posterior septum, whether complete or incomplete, whether the vaginae are of equal or unequal size, or one patulous and the other occluded.

Double vagina has heretofore received little consideration. It is hardly of less importance clinically than double uterus, and then the malformations of the uterus under discussion are more frequently associated with a double than a single vagina. Of the 270² cases the writer has studied, 144 or 53¹/₈ per cent. were associated with a duplex condition of the vagina, and furthermore, this duplex condition of the vagina sometimes gives rise to many distressing symptoms and in a few cases has been the cause of the death of the patient. Frequently it has interfered with coition, menstruation and labor so that operative procedures have been required.

The writer has purposely abstained from theoretical discussions, leaving that for some future occasion, and has confined himself to the historical, clinical and statistical study of the subject.

First, then following the line of study as indicated in his description of the tables above, he has to present some facts relative to 100 cases of pregnancy, gestation, and delivery. Tables A, B and C are sufficiently plain as to require no explanations.

The following facts regarding twin and triplet pregnancies are found, viz.: Fifteen women were pregnant of twins seventeen times. The forms of the uteri were as follows: Bicornis, vagina single, 10 women pregnant 11 times; bicornis, vagina double, 2 women pregnant 2 times; bilocularis, vagina single, 3 women pregnant 4 times.

One woman four twins twice and triplets twice. This woman had a bicornute uterus with double vagina, and died of rupture of the uterus in the last labor.

It is pertinent to enquire what are the dangers

¹Todd's Cyclopaedia of Anatomy and Physiology, Vol. v. p. 678.
²Cases in the former article included.

TABLE A—*Showing facts regarding pregnancy in the different forms of double uterus and vagina.*

FORM OF MALFORMATION.	No. women pregnant	No. pregnant	No. Natural deliveries.	No. artificial deliveries.	No. not stated	Abortions or miscarriages	No. of deaths of mothers.	REMARKS.
Uterus double, vagina single.	71	161	122, or 75.5 %	22, or 13.6 %	3	22, or 13.6 %	20, or 28.1 %	
Uterus double, vagina double.	20	85	36, or 40 %	17, or 26 %	22	10, or 16 %	8, or 27.5 %	
Details as to classes under the same heads as above.								
Uterus bipartitus, vagina single.	3	7	4	2	1	1	1, or 33.3 %	
Uterus bipartitus, vagina double.	1	1	1					
Uterus unicornis, vagina single.	3	6	4				3, or 100 %	
Uterus bicornis, vagina single.	42	120	80	11	4	23	11, or 26.1 %	26 women had natural deliveries, 10 women had artificial deliveries, 1 missed labor, 10 women miscarried.
Uterus bicornis, vagina double.	19	50	34	10	1	13	6, or 31.5 %	Number of women who miscarried, 8.
Uterus didelphys.	4	4		2		2		These cases were included in the class immediately above.
Uterus bilocularis, vagina single.	18	39	34	4			5, or 27.6 %	Number of women having natural deliveries, 14.
Uterus bilocularis, vagina double.	8	19	14	5	1		2, or 25 %	Number of women having natural deliveries, 3; pregnant when seen, 1.

TABLE B—*Showing the number of deaths, and the cause thereof, as a result of pregnancy and delivery in double uterus and vagina.*

FORM OF MALFORMATION.	No. of Deaths	Septicæmia	Puerperal Fever	Peritonitis.	Hæmorrhage. Post-partum.	Hæmorrhage from vicious resection of the Placenta.	Collapse.	Hæmorrhage. Placenta prævia.	Rupture of the Uterus.	REMARKS.
Uterus bipartitus, vagina single.	1								1	
Uterus unicornis, vagina single.	3			1					2	The death from peritonitis followed a normal delivery.
Uterus bicornis, vagina single.	11	1	1	1	1				4	Puerperal endometritis, 1; pneumonia, 1; eclampsia, 1; arterial embolism, 1.
Uterus bicornis, vagina double.	6	1		2			1			Rupture splenic abscess, 1; not stated, 1.
Uterus bilocularis, vagina single.	5				1	1		1	1	1 from metro-peritonitis, and 1 polypus of the heart.
Uterus bilocularis, vagina double.	2			1					1	1, eclampsia during labor.

TABLE C—*Showing the means employed to effect delivery where artificial means were employed.*

FORM OF MALFORMATION.	Number of Cases.	Forceps.	Turning.	Laparotomy.	Cæsarean Section.	Incision of Septum.	Cephalotripsy.	Manual Delivery.	REMARKS.
Uterus bipartitus, vagina single.	2	2							
Uterus bicornis, vagina single.	11	4	2	1					Fœtus removed piecemeal, 1; not stated, 3.
Uterus bicornis, vagina double.	10	1	2				1	1	Fœtus removed piecemeal, 1; accouchement force, 1; not stated, 3.
Uterus bilocularis, vagina single.	4	1	1		1				Croche, 1; 1 on account of abnormal position of uterus.
Uterus bilocularis, vagina double.	3				1	2			Cæsarean section was done after death of mother from eclampsia.

to be feared from pregnancy occurring in those forms of malformation of the uterus? In the first two forms, viz.: bipartitus and unicornis, rupture of the uterus. In the first on account of the defective development of uterine tissue, its walls may not develop as the period of gestation advances. They are prone rather to dilate as the embryo grows and finally reach a point where they

are not sufficiently strong to resist the pressure from within and rupture. In the second form we have three elements of danger either one of which may lead to rupture of the uterus.

1. The rudimentary horn may become pregnant and rupture from the same cause as mentioned in the preceding paragraph, or the fœtus attaining full growth may find no way of escape

from the uterus and a rupture of the organ occur as a result of labor-pains.

2. The unsymmetrical development of the uterine cornua predisposes it to rupture sometime during the period of gestation or in labor.

3. The oblique position in the pelvis in which the horn develops may remove the axis of the uterus from that of the vagina and thus render labor not only difficult but natural labor impossible, and here rupture may result from long continued pressure of some portion of the fœtus upon the uterine wall conjoined with the violent contractions of the uterus in its efforts to effect delivery. The last mentioned element of danger is probably more theoretical than real, for the writer has been unable to find any reported cure of rupture of the single horned uterus where the pregnancy occurred in the developed horn, while he has the histories of two cases where rupture resulted from impregnation of the rudimentary horn.

In uterus bicornis troubles following delivery are the most prolific causes of the death of the mother. This may be accounted as due to the large number of difficult labors and the imperfect drainage of the uterus following labor on account of its unfavorable position in the pelvis. Rupture of the uterus is next in frequency as a cause of death. One case occurred because of the impaction of the head of the fœtus and the prolonged effort of nature to expel it, and in three cases where each fœtus developed in a rudimentary horn.

Hæmorrhage was the chief cause of death in patients having uterus bilocularis. Vicious attachment of the placenta and irregular uterine contractions subsequent to labor are mentioned as the predisposing causes of the hæmorrhage.

As a second division of our subject we may consider those cases having a vaginal septum with the uterus normal and all the subjects pregnant. Here we have the histories of 22 cases. The vaginal septa presented various forms and shapes and are described by reporters as crescentic, pyramidal and complete antero-posterior vertical septa. When complete they extend from the introitus vaginæ to the cervix uteri or to the upper extremity of the vaginal tube to one side of the cervix. The septum is covered by mucous membrane upon either side and continuous with the mucous membrane of the vagina. Between the two layers of mucous membrane are submucous and cellular tissue, the latter of which serves to fasten it in its position antero-posteriorly in the vagina. Considerable muscular tissue is sometimes present between the layers of mucous membrane, and at times fibrous tissue predominates. Any part of the septum from the vaginal entrance to the cervix of the uterus may be deficient, so that the forms and shapes already mentioned may be assumed. In this class we have twenty-two

women pregnant twenty-eight times. One woman was pregnant several times, with every labor normal. The septum interfered with labor in 12 instances. Of these the septum was torn through in labor in 4, incised in 7, and severed by a thread in 1. In 3 cases considerable hæmorrhage followed the incision. There were no deaths. Seven patients had normal deliveries. In the artificial deliveries the following means were used, viz.: Crochet, 1; delivered through the rectum after incision, 1; forceps, 4; and manual change of position of the child in 1 case.

Our third division relates to congenital malformations of the uterus where the vagina is single or double and pregnancy has never occurred. Here we have the histories of 90 cases. The chief interest the writer has found in the study of this class of cases has been in the percentage of each form of malformation found, the departures from the normal in the anatomical condition, the anomalies of menstruation incident to them, and lastly, the diseased conditions found to exist. There were of the various forms reported: Of uterus bipartitus, vagina single, 7 cases, vagina double, 1 case; of uterus unicornis, vagina single, 11 cases, vagina double, no case; of uterus bicornis, vagina single, 32 cases, vagina double, 28 cases; of uterus bilocularis, vagina single, 5 cases, vagina double, 6 cases. Total—vagina single, 55 cases; vagina double, 35 cases. In uterus bipartitus the vagina was found to be normal in but a single case and double in one. In all others it was either short, a cul-de-sac, or entirely absent. The adnexa were found normal in 3 cases, and either rudimentary or imperfectly developed in others. The uteri varied in size, shape and development. In some cases they were simply rudimentary without a canal, in others without any communication with the ovaries through the Fallopian tubes. In one case the uterus was sufficiently well developed to admit of normal menstruation, and in this instance the reporter states there were three ora, and that the menstrual fluid escaped from all of them simultaneously.

Concomitant to an imperfectly developed condition of the uterus and vagina was a like condition of the adnexa. Sometimes the imperfections were found in the tubes and at other times in the ovaries. The anomalies of menstruation were dependent upon those of the organs already described. The nearer approach to perfect development of all the organs involved the more nearly normal was the performance of the function. Menstruation was absent in three cases, vicarious in one where there was no uterine mucosa, but normal tubes and ovaries. In one in which there was no normal flow, but distressing molimina, the latter entirely disappeared on removal of the ovaries.

There does not seem to have been any record of a special proneness to any one disease.

In uterus unicornis we find no instances where

this malformation was associated with a double vagina. The most marked feature to be found in this class is an occasional rudimentary horn, also a rudimentary condition of the tube and ovary upon the side in which the cornus is absent. A number of cases of entire absence of the tube, ovary and kidney upon the imperfect side are found. A marked deflection of the one-horned uterus toward the side in which it develops frequently exists. But few details are given respecting menstruation, but what are, show that this important function is performed irregularly or is entirely absent.

Of the 90 cases of women who have never conceived and who had malformations of the uterus of the forms under discussion, 60 of them were of uterus bicornis. Here is the middle ground between the normal and the greatest deviation from the normal, and here will centre the chief interest of the practitioner. In the 28 cases in which the duplex vagina occurs will be found nearly every variation incident to this anatomical abnormality. In some instances the vagina is divided into two parts, equal or unequal, by a complete septum. Atresia of one side occurs in one instance, and in several instances a partial septum incompletely divides the tube.

There are 15 instances of complete septum and 4 in which it is incomplete, 1 of atresia of one vagina, and 8 in which it is not stated, but is probably complete. As great a variation in the form of the uterus was noted. Todd's accuracy in his description of this form of malformation is here verified. No cases of uterus didelphys are recorded in this table. The histories from which the table was compiled are too meagre, in some instances, to enable the compiler to accurately state the number in each variety in this class; nor, indeed, is it important.

It was observed that sometimes the os was single and sometimes double, and that in quite a number of instances there was atresia of one os and a resultant hæmatometra. A rudimentary horn was not infrequently present, and when found it had usually as concomitant a rudimentary ovary and tube. The facts regarding menstruation are not sufficiently complete to be entirely satisfactory, yet there are some points of interest. Sometimes the flow proceeds from both sides of the bicornute uterus simultaneously, and at other times the uteri alternate in the performance of this function; when they do menstruation occurs either every two weeks or every four weeks. In the light of these facts who can question the possibility of the impregnation of one horn when the other horn contains an ovum in process of development.

Hæmatometra is met with more frequently in this class than in all others. Cystic degeneration of the ovary seems to be the only disease which occurs with more than usual frequency.

In uteris bilocularis there is the least departure from the normal development. The adnexa are less frequently rudimentary or absent, the external genitals more frequently well developed and the performance of the menstrual function is not so often imperfect or difficult.

There are recorded in this table 6 cases in which in this class the vagina is duplex. In all of them the septum was complete and no instance of atresia of any one of them found. There are 6 cases in which there are two ora, 3 having two cervixes, 2 of single os, 1 of atresia of the os, and 2 not stated. One case had two cervixes and a single os. Here a hæmatometra developed. There is quite a variation in the external form of the uterus. Sometimes no departure from the normal could be detected in the body of the uterus by conjoined manipulation, in others a groove marked the line of division of the organ, and in others there was a depression at the center of the fundus. The vaginal touch and uterine sound proved the most valuable means of diagnosis.

In but four instances are there details given of the state of the menstrual function. In three of these it was performed normally, and in one normally, except that it was painful. The following morbid conditions were found: 1 of cyst of Fallopian tube; 1 gonorrhœa with resulting parametritis; 1 cancer of the uterus.

The fourth table I have compiled and to which I wish to refer to here, is made up of the histories of 12 cases of non-pregnant normal uteri associated with double vagina. One vagina was a cul-de-sac in seven instances. Inflammatory disorders of the uterus and vagina existed in six instances. The septum was incised in three, and severed by the galvano-cautery in two, and all recovered. Disordered menstruation was present in 3 cases. The uterus was normal in all cases but one and in that one it was undeveloped.

The following is a statement of the number and per cent. in each form of malformation, including those reported in my former paper, viz.: Uterus bipartitus, 14 cases, or 5.2 per cent. of all cases; uterus unicornis, 18 cases, or 6.7 per cent. of all cases; uterus bicornis, 175 cases, or 65.3 per cent. of all cases; uterus bilocularis, 68 cases, or 22.7 per cent. of all cases; unclassified, 2 cases. Total number of cases 270. Number of cases of double uterus and vagina, 144, or 47.3 per cent.; number of cases of double uterus, 126, or 41.4 per cent.; number of cases of double vagina, 34, or 11.1 per cent. Total number of cases, 304.

Hæmatometra.—Twenty cases in all are recorded in the lists we are studying. One was found two weeks after delivery and 19 in cases in which pregnancy never occurred. In but a single instance do we find it associated with hæmatocolpus. In one instance nature after a time performed a cure, a perforation occurring in the septum between the cornua so that the retained fluid escaped

into the pervious uterus and thence found its way into the vagina. A perfect recovery took place.

No instances are recorded where hæmatometra or hæmatocolpus was discovered where there was double vagina alone, and but a single case occurred in a woman who had ever been pregnant. This woman had borne twelve children, the last one three weeks before admission into the hospital. Upon examination a hæmatometra was discovered, opened by the finger-nail and the patient recovered. One case of rupture of the uterus is recorded, resulting from hæmatometra. A hæmatometra had been discovered and punctured and part of the fluid evacuated. Five days later the patient died suddenly of rupture of the uterus. Of the cases of hæmatometra recorded 19 were of uterus unicornis, and 1 of uterus bilocularis. Seventeen of them were operated upon, 9 died and 8 recovered. The means employed, and results, are as follows: 6 cases of puncture with trocar, 5 deaths, 1 recovery; 2 cases trocar first and bistoury later, 1 recovery and 1 death; 5 cases incision with bistoury, 4 recoveries and 1 death; 1 opened with finger-nail, recovered; 1 opened with sound, died; 2, means not stated, 1 died, 1 probably recovered; 1 case nature cured. The causes of death in 6 cases is states as peritonitis; 1 empyæmia; and 2 not stated. In one case imperfect drainage resulted in suppuration, free drainage and irrigation effected a cure. In another puncture was followed by fever, which was quickly relieved by free incision.

Hæmatocolpus is found in three instances, once occurring with hæmatometra, the details of which I am unable to obtain. A second one is found with no details. The third case was one of acquired hæmatocolpus. It was tapped four times. After the last tapping a peritonitis developed and the patient died.

Rupture of the Uterus.—Nine cases of rupture of the uterus are recorded. Six were of uterus bicornis, two of uterus unicornis, and one of uterus bipartitus. All but one occurred as a result of pregnancy. The exceptional case was one of uterus bicornis, in which there was atresia of one horn and a hæmatometra developed. It was punctured and the menstrual fluid allowed to escape. Five days later the patient was suddenly seized of a violent pain, which lasted some time, when she had the feeling as of something giving way. Death soon followed and the autopsy revealed a rupture of the uterus of the horn in which the menstrual fluid had been retained.

Of the 8 cases pregnant in which rupture occurred, in 3 it was the first pregnancy; in 1 the twelfth pregnancy; but the first in the horn ruptured one previously referred to; 1 in the fifth pregnancy and first in the horn ruptured; 1 in the fourth pregnancy and first in the horn ruptured; 1 not stated; 1 in the fifth pregnancy, that of triplets.

In the last case the rupture occurred in the forty-first hour of labor, all the preceding labors having been difficult. The rupture in this case was doubtless due to the head having been in such a position that it could not advance.

The immediate cause of death was peritonitis in 4 cases; hæmorrhage in 3; not stated in 2.

No operative measures were employed in 6 cases. In 2 the children were delivered by forceps. Every patient in which the rupture occurred died. No operative procedures were resorted to to save the patients after the rupture occurred.

The records show a case in which laparotomy was done to remove a supposed tumor. A pregnant rudimentary horn was found. A month later the abdomen was opened, the horn extirpated and the patient made a good recovery. In another instance pregnancy occurred in a rudimentary horn, symptoms of labor appeared and passed away. Six months later the woman died of plithisis, when autopsy revealed the true condition. The foetus had been dead some time and was partly absorbed.

These two cases furnish us a hint of the possibilities of cure in laparotomy, and in electricity to produce death of the foetus. It is not surprising that the expectant treatment was adopted in the majority of the cases of rupture; for they occurred before the benefits of laparotomy were fully understood, and some of them, indeed, before this procedure had ever been employed for the relief of similar conditions. Then, too, it must be remembered, the true nature of some of the cases was only determined upon autopsy. The question will naturally arise as to the operative measures to be adopted when a pregnant rudimentary horn is discovered. The solution of this question will doubtless depend upon the anatomical condition present and the time in the period of gestation it is found. If the examiner can make out clearly a pregnant rudimentary horn with a long pedicle, and in the early months, laparotomy will doubtless be generally chosen. Should the rudimentary uterus be closely attached to its fellow then it may be necessary for the operator to choose between Porro's operation and the use of electricity to produce the death of the foetus.

The highly favorable results shown by recent writers attending the use of electricity will strongly tend to popularize the procedure if indeed not to stamp it as the one above all others to be employed in all cases of pregnancy of the rudimentary horn and of extra-uterine pregnancy in the earlier and middle months. After the rupture of the uterus and the discharge of its contents into the abdominal cavity laparotomy affords the only hope of recovery. When the full period of gestation is reached without a rupture, and labor is attempted, the same rules must govern the treatment as in tubular pregnancy, and when rupture occurs during labor from obliquity of the uterus,

impaction of the foetal head, or from non-development of some portion of the uterus, and the os be pervious and in communication with the vagina, the same procedures should be adopted as in rupture of the uterus occurring where there is no malformation. Simon's case¹ shows one point of particular interest. A rudimentary uterus having no communication with its fellow became pregnant and ruptured. The autopsy revealed an absence of a corpus luteum in the ovary corresponding to the pregnant horn, but a fresh one in the ovary of the opposite side. This instance strongly supports the theory of the migration of the ovum, either before or after it has been pierced by the spermatozoa, to the mouth of the tube upon the opposite side and thence through the tube to the rudimentary horn.

NASAL MYXOMATA.

Read before the Chicago Medical Society, September, 1888.

BY W. E. CASSELBERRY, M.D.,

PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, AND OF LARYNGOLOGY AND RHINOLOGY, IN THE CHICAGO MEDICAL COLLEGE, MEDICAL DEPARTMENT OF THE NORTHWESTERN UNIVERSITY.

Nasal polypus is an ancient subject, but considering its frequency, the discomforts and dangers to which it subjects the sufferer, the difficulty

of such associated maladies together with the polypi is the "key-note" to the proper and effective handling of the patient. Recognition of the exact points of origin of the neoplasms is essential to a clear understanding of their etiology and treatment. The outer wall of each nasal cavity is rendered especially uneven by the three turbinated bones, their margins of attachment being horizontal one above the other, which leaves intervening spaces, called respectively, the inferior meatus, between the inferior turbinated body and the nasal floor, the *middle meatus*, between the middle and inferior turbinated bodies and the superior meatus, between the superior and middle turbinated bodies. In the outer wall of the middle meatus is the ethmoidal fissure or *hiatus semilunaris*—a crescentic opening about two millimetres in width and two centimetres in length, its

Fig. 1.—Representing the outer wall of the left naris with the middle turbinated body turned upward to show beneath the hiatus semilunaris, to the edges of which polyps are frequently attached.

of radical extirpation and the consequent liability to recurrence, it may well be reviewed in the light of modern methods.

The disease does not exist as a primary affection, but is always associated with some other nasal malady which stands to it in the relation of cause or as a complication. Indeed the removal

convexity being directed downward and forward, (Figure 1.) The antero-inferior boundary of the fissure is a sharp edged ridge which, from its hook-like curve, is termed the unciform process of the ethmoid bone. The postero-superior boundary is formed chiefly by the *bulla ethmoidalis* which is an ethmoidal cell with its wall bulged toward the septum and downward. The

¹ Zeitschrift für Geburtshülfe und Gynäkologie, 1877-78.

fissure itself is an opening into the whole length of the side of the *infundibulum*, which is an elongated crescentically curved funnel shaped cavity communicating through its upper and smaller end with the frontal sinus and through its lower and larger extremity with the antrum of Highmore, entering this cavity in conjunction with the main opening into it from the middle meatus—the *ostium maxillare*.

Above the bulla ethmoidalis, between it and the top of the middle turbinated bone, is another, smaller, fissure which leads into the ethmoid cell of the bulla.

All of these parts lie high up, beneath the middle turbinated bone which hangs down over them like a curtain.

Well developed myxomata rarely spring from flat surfaces. They arise wherever there is a free edge covered by mucous membrane whence they hang by a pedicle. Zuckerkandl (*Anatomie der Nasenhöhle* S. 64 *et seq.*), cited by Mackenzie,¹ has furnished the most definite information of the exact points of origin of nasal myxomata in the publication of the post-mortem observation of forty-two distinct growths in which the deep origin was ascertained by the gradual removal of the bony parts. Of these forty-two growths, twenty-nine grew from the middle meatus, including two from within the *infundibulum*, four from the middle turbinated body, three from the superior meatus and the balance of six scattering as, from the Antrum of Highmore two, *ostium frontale* one, *ostium sphenoidale* one, *ostium ethmoidale* one, and upper tubinated body one.

Of the twenty-nine growing from the middle meatus, seventeen were attached to the edges of the *hiatus semilunaris*, the crescentic fissure just described. These observations are in perfect accord with the precise clinical observations recently rendered possible through the extension of our field of vision within the nasal fossæ by the retracting power of cocaine.

It is thus shown that *two-thirds* of all nasal myxomata originate from the middle meatus, beneath the middle turbinated body, and that approximately *two-thirds* of this number take origin from the edges of the *hiatus semilunaris*.

With this knowledge and judging from the superficial position of the neoplasm and the direction of its pedicle toward attachment we can be reasonably certain of the deep point of origin even when such is not visible and can often destroy the very root of the growth by insinuating a properly curved cautery point-electrode to the spot.

The attachment, wherever located, may involve only the mucous and submucous tissue, or it may extend too and involve the underlying bone. The nasal mucous membrane consists of two layers: a superficial mucous stratum, and a

deep fibrous layer, which latter has the position and functions of periosteum or perichondrium. As first asserted by Stoerk² mucous polypi or myxomata, which are connective tissue growths, arise chiefly from the mucosa or superficial layer included with which is a connective tissue sub-mucosa, but in parts of the upper or olfactory tract the mucous and fibrous (periosteal) strata are closely adherent and it is easy to conceive of the attachment penetrating subsequently to the immediately adjoining periosteum (fibrous layer) and thence to the bone.

Furthermore, it is asserted by Woakes³ that "these two layers constitute a muco-periosteum which unseparated, dips into the spongy structure of the bone and lines the cells and their osseous dissepiments." In this way the mucous membrane element is introduced into the very interior of the bone and hence may arise myxomata from within the cancelli of the bone of course having bony attachments. Being connective tissue growths it is entirely possible also they may at times originate directly from the periosteum without the intervention of the mucosa although a fibroma or at least a fibromyxoma is more likely then to result.

Etiology.—The most common complication acting also in a causal relation to nasal polypus is hypertrophic rhinitis. Hyperæmia and all which tends to cause congestion will excite hyperplasia and predispose to the formation of distinct neoplasms. Various factors may influence the perversion of a simple hyperplasia of the mucous elements into myxomatous formations.

Hereditary or constitutional diathesis, of a nature too subtle for positive demonstration, may predispose certain families or certain members of a family, as is the case with other neoplasms. It is probable, however, that more frequently variations in the physical conformations of the nostrils determine the involvement of particular areas in the hypertrophic process which occurring at these points is prone to assume the myxomatous form.

On flat surfaces, *e. g.*, the inferior turbinated body, true polypi rarely develop, but sessile polypoid excrescences—minute myxomatous neoplasms, called "polyp-buds," are a common perversion of the hypertrophic process in this locality. These show little disposition to become fully developed polypi. But when hyperplasia occurs upon a free edge whence portions of mucous membrane become pendulous the conditions are favorable to the production of a circumscribed œdema. The pendulous position with gravity simply favors the exudation of a maximum of mucin containing serum with a minimum of connective tissue cell proliferation. Consequently whatever favors hypertrophy over such free edges, as the borders of the *hiatus semilunaris*, middle turbinated

² Die Krankheiten der Nase, 1880, S. 99.

³ Nasal Polypus, etc., in relation to Ethmoiditis, 1887, p. 9.

¹ Diseases of the Throat and Nose, Vol. ii, p. 362.

body, etc., acts as a direct cause of mucous polypus. This area is less frequently involved in the hypertrophic process than the lower turbinated bodies, but the same causes, *e. g.*, repeated, acute rhinitis, dust or vapor irritants may affect it either directly or through extension by continuity of surface.

Stenosis, whether induced by hypertrophy of the inferior turbinated bodies, septal deflections or excrescences, results in defective drainage. Mucopurulent secretion, imprisoned and decomposing in the middle meatus and around the middle turbinated body, excites irritation and furnishes the most favorable soil for polyp growth.

Very narrow nostrils, because more readily stenosed, are predisposed, in this manner, to myxomata, and peculiar curvatures or deformities of the septum and middle turbinated bodies by obstructing drainage have a like effect. In one instance, a congenitally deformed middle turbinated bone encroached tightly upon the septum and even pushed it far to the opposite side, preventing drainage from above and causing irritation of surrounding parts.

The influence of hypertrophic rhinitis on the etiology and treatment is well illustrated in the following history.

Miss T—, æt. 10 years. Total obstruction of the left nostril of one year's duration.

Fig. 2.

Status Præsens.—Examination July 16, 1887. Enormous hypertrophy of the inferior turbinated bodies. Numerous polypi are closely impacted between the turbinated bodies and the septum they proceed from the middle meatus and are continuously imbedded in a mass of thick viscid mucopurulent secretion. (Figures 2 and 3.) The polypi seemed secondary to the hypertrophic rhinitis and defective drainage. On the right side hypertrophy was present but was insufficient to obstruct the drainage and no polypi were visible.

Operations first by the cold wire snare resulted in the removal of numerous growths, during re-

peated sittings, but without improvement. The polypi developed as rapidly as removed, springing up like mushrooms in the soggy soil, maintained by the imprisoned secretions. The inferior turbinated body was next cauterized along its entire extent being reduced in front where it especially interfered with vision, instrumental passage and drainage, almost to a rudiment. One

Fig. 3.

was enabled then to trace the tumors to their exact seat of attachment in the immediate vicinity of the *hiatus semilunaris* and to thoroughly eradicate them by reaching that position with a cautery point. No recurrence. Cure complete.

This patient was but 10 years of age. Myxomata are said to be rare before puberty but are probably only relatively as rare as persistent rhinitis at the same period.

Again, Mr. P—, æt., 45, catarrhal symptoms

Fig. 4.

Fig. 5.

for some years; obstruction of the left nostril for one year.

Status Præsens.—Examination March 18, 1887. A single polypus proceeds from the left middle meatus and is traceable in the direction of the *hiatus semilunaris* to the edge of which it is evidently attached. (Figure 4.) The middle turbinated body is so hypertrophied as to reach across

to the septum and to obstruct drainage from the middle meatus even after removal of the polypus.

The myxoma was removed by the cold wire snare and its base cauterized by the insertion of a flat knife-electrode upward beneath the middle turbinated body to the point of attachment. Subsequent reduction of the hypertrophic rhinitis and the establishment of proper drainage. No recurrence.

The case of Mr. M—, æt. 25 years, referred by Dr. N. S. Davis, Jr., is remarkable on account of the multiplicity of the neoplasms and the gravity of the consequences.

Both nasal fossæ were literally packed with myxomata and fibro-myxomata. Complete suspension of nasal respiration for years; stupidity of facial expression incident to mouth-breathing; pharyngitis and predisposition to acute bronchitis and asthmatic paroxysms; total incapacity for business usefulness. Previous courses of treatment had failed.

After removal, one by one, of a number of polypi, the inferior turbinated bodies were found to be greatly hypertrophied. They obstructed respiration and drainage, interfered with the transmission of light to the superior and posterior parts of the fossæ and prevented the passage of instruments.

After reduction of these bodies by the galvano-cautery snare and knife electrodes it was possible by the same means to extirpate the bases of the numerous myxomata, which originated from the middle meatus, middle turbinated body, and from the superior meatus descending posteriorly. Result perfect. Examination after one year shows not the slightest recurrence, and nasal respiration is always free.

Septal excrescence is another complication acting also in a causal relation to nasal myxomata. These deformities of the septum are usually found on the sutural lines of the component bones and cartilages, and are osseous or osseo-cartilaginous in structure. The most frequent location is the sutural line of the vomer, and superior maxilla and cartilaginous septum just within the anterior nares and close to the floor of the nose. This, as well as other conditions, finds illustration in the following case.

Mr. B., æt. 32 years, has suffered from nasal obstruction with polypi since 1872. In 1873, and from 1875 to 1880, a number of unsuccessful attempts at removal were made by the old method of "going it blind" with a pair of forceps. Operations by the cold-wire snare and forceps under illumination followed, in 1881, 1885, and 1886.

Status Præsens.—Examination July, 1887. Several myxomata spring from beneath the left middle turbinated body, and from near the roof of the left naris. Both inferior turbinated bodies are hypertrophied, and on the left side a prominent

spur or excrescence projects from the septum, meeting the turbinated body and causing obstruction of the left nostril independently of the polypi. (Fig. 5.) Polypi exist also on the right side, and large myxomata, together with polypoid degeneration of the septum and of the posterior ends of all the turbinated bodies occlude the posterior nares. (Fig. 6.) There is necrosing ethmoditis of Woakes, dead bone and fetid discharge.

Fig. 6.

The septal excrescence obstructs respiration, prevents drainage, interferes with vision, and renders it impossible to pass instruments to the seat of disease. It was easily removed by a saw which I found convenient to devise for the purpose. The floor of the nose just within the anterior nares is not a perfectly horizontal plane, but is curved, with the convexity directed downward. The septal deformity is close to the floor and conforms to this curve, consequently a straight saw often cannot be introduced, while one curved, likewise, in conformity to the floor of the nose meets with no obstruction. (Figs. 7, 8, and 9.) The

Figure 7.

teeth of this saw, also, cut upon the pull and not upon the push, an advantage, for the reason that on the push it is sometimes necessary to insinuate its distal extremity carefully between parts while on the pull its passage is free. Next followed reduction of the hypertrophies, the polypi being at the same time removed as fast as access could be gained. A fine-point electrode was insinuated beneath the middle turbinated body to one seat of origin, the

edge of the *hiatus semilunaris*, and finally, having tied the velum forward, a properly curved point electrode was introduced through the nasopharynx and all remaining roots and small polypi which were located high up and posteriorly in the region of the superior turbinated body were destroyed.

One year after cessation of treatment Mr. B. writes as follows: "I have remained well, as far as any return of the polypi is concerned. I enjoy free respiration through both nostrils. On breathing with force through both nostrils I am unable to feel the slightest obstruction."

largement of the anterior end of the middle turbinated body. Polyp-buds may form over the surface and ultimately develop into myxomata, or a center of proliferation of the mucous element within the body of the bone may so develop as to cleave asunder the middle turbinated body, leaving a fissure down its center from which will protrude the polypi—a condition of which the following case is an illustration.

Miss P., æt. 20. Catarrhal symptoms for years.

Status Præsens.—Examination Sept. 11, 1886. Atrophic naso-pharyngitis and horribly foetid in-

Figure 8.

Fig. 10

Figure 9.

Necrosing ethmoiditis of Woakes¹ also figures as a persistent cause and complication of nasal polypus. It involves the nasal tributaries of the ethmoid bone, especially its process the middle turbinated body. The *mucoperiosteum*, already described as dipping, unseparated, into the spongy structure of the bone, undergoes inflammation, which cause the mucous element to proliferate in the direction of myxomatous formations and the periosteal stratum, also inflamed, to result in necrosis of the subjacent bone.

The earliest appearance of the disease is an en-

crustation. The right middle turbinated body is much enlarged and has the appearance of two bodies because of the cleavage; (Fig. 10.) From this cleft protrude several small polyp, or polyp-buds, and others exist over the surface and in the immediate vicinity. A fine probe inserted into the cleft detects dead bone.

The removal of the entire necrosing turbinated body is sometimes practiced in such cases. In this instance it sufficed to cauterize thoroughly, introducing a knife electrode far up into the cleft and in like manner destroying diseased parts of the surface.

¹ Nasal Polypus, etc., In Relation to Ethmoiditis 1887.

Under this and other appropriate treatment, the symptoms have been so ameliorated as to cease to be troublesome, and the polypi have not recurred. Necrosis once established, however, becomes an important factor in the persistence of inflammation of the soft parts and prolonged treatment may be necessary to eradicate the disease.

Necrosing ethmoiditis may exist without polypus, and polypus without necrosis. The assertion of Dr. Woakes that "when polypus exists necrosis is also present," is not confirmed by my experience, inasmuch as in the majority of the cases herewith reported the most careful search failed to detect necrosis.

Still another complication is illustrated by the case of Miss McC., referred by Dr. E. J. Gardiner. Multiple polypi occlude both nares, and extend backward to the naso-pharynx. An *hypertrophic tonsil* was necessarily abscised before access for light and instruments could be gained. Hypertrophic rhinitis also was reduced by the usual means. The case is still under treatment, but looks favorable to a permanent recovery.

Incrustation and infiltration of a myxoma with calcareous deposits may cause it to resemble an osteoma.

In such a case, observed in an aged person, the whole right naris above the inferior turbinated body was occupied by a fixed and impenetrable tumor. Excised portions of the growth resembled thick egg-shell, covered on its outer surface by mucous membrane and on its inner concave surface with myxomatous tissue, as if, in the course of years, the central part of the polypus had been absorbed, while calcareous deposition occurred in the enveloping membrane. The neoplasm was so firmly fixed to the nasal bones that it was deemed best to remove only a part of it, sufficient to permit of free nasal respiration. It evinces no disposition to redevelopment.

Other nasal neoplasms, by maintaining irritation and obstruction to drainage, may excite the development of myxomata. Dr. Christian Fenger⁵ has described an osteoma which after removal was found to have attached to it several polypi.

In like manner myxomata may exist in mere association with primary carcinoma of the nasal and accessory cavities. In a case seen through the courtesy of Dr. Boerne Bettman, in 1887, the right nasal cavity was filled with a soft pulsatous ulcerated mass, which involved the antrum, orbit, and other accessory chambers. Carcinoma or sarcoma was evident. When first seen by Dr. Bettman myxomata only were visible in the naris, and several were removed by a snare. It is most probable that the malignant neoplasm originated in one of the accessory cavities and while extending to the naris excited a growth of myxomata.

Of course the transition of a benign myxoma into a malignant sarcoma or carcinoma cannot be regarded as impossible, since myxomata are histologically related to sarcomata, yet cases of myxoma which even suffer repeated surgical manipulation are so common, and such apparent transitions so rare, that, in the latter case, it were more reasonable to assume that the malignant disease arose primarily and that its presence excited a contemporaneous development of myxomata, as might any other irritant.

Physical Characters.—The form, aspect and consistence of a myxoma has been compared to a grape pulp. The natural shape is pyriform, but this is often varied by pressure. When small it is sessile, but it becomes pedunculated by gravity as development proceeds, and the point where the pedicle is confounded with the tissues of attachment is known as the "root." The color varies according to vascularization from gray to yellow, and from yellow to pink and red.

Pathological Histology.—A typical myxoma or "myxoma hyalinum" resembles in structure the vitreous body of the eye and the gelatin of Wharton of the umbilical cord. Microscopically there are observed either a few roundish cells, as in the vitreous body, or scattered fusiform and stellate cells which send off anastomosing trabeculae, as in Wharton's gelatin, or both together, and these are imbedded in a large quantity of a homogeneous gelatinous mucin containing intercellular substance. Acetic acid causes opacity by the precipitation of mucin in a finely molecular state. Preparations hardened in alcohol or chromic acid give in undefined portions granular and fibrinous appearances.

Macroscopically the "myxoma hyalinum" is translucent, almost transparent, and of a pale yellowish hue.

But myxomata rarely appear in this purely typical form, the "myxoma hyalinum" being prone to transformation into allied histological structures or to be represented from the beginning by one of its modified forms. Of these the most common is the myxofibroma, which contains a greater but variable quantity of fibrous tissue. Those which are ordinarily called myxomata usually contain enough of the fibrous element to include them, strictly speaking, within the class of myxofibromata.

Multiplication of its round cells imparts to the myxoma a whiter, denser, less gelatinous and more medullary aspect, and it is then named "myxoma medullare."⁶ If the spindle cells increase the transformation is into myxosarcoma; when fat is an element it becomes a myxolipoma; so also do we have the myxochondroma. Between these various neoplasms it is sometimes impossible to draw a distinct line of demarcation.

Myxomata are connective tissue growths, and

⁵ Living and Dead Osteomas of the Nasal and Accessory Cavities. Jour. Am. Med. Assoc., Vol. xi, No. 6.

⁶ Perls, Allgemeine Pathologie, S. 247

in addition to their occurrence as nasal polypi originating from the mucous and submucous tissues of the nose, they may originate from these structures elsewhere or in the intermuscular septa, nerves, subserous fat and periosteum.

Symptoms.—The chief symptom is nasal stenosis which increases with the development in size and number of the polypi, until complete obstruction of one or both nostrils results. Mucous or muco-purulent discharge, cephalalgia, aural complications and other symptoms of a catarrhal nature, together with those incident to mouth-breathing, are observed. To quote the words of a sufferer: "It affects the sight, the hearing, the taste, and the smell of course." Spasmodic asthma, paroxysmal cough and sneezing attacks are among the reflex phenomena which are occasionally excited. For diagnostic purposes it is usually only necessary to look with a good light and to feel with a probe in order to establish correspondence with the physical characters just described, but more rarely an accurate knowledge of all pathological states is essential to a precise diagnosis.

The treatment has been outlined in the relation of the cases. It consists first in the establishment of free nasal passage for respiration, drainage, vision and instrumental manipulation, and to this end in the reduction of hypertrophied turbinated bodies, the removal of septal excrescences, hypertrophied tonsils, etc.

To reduce the hypertrophied turbinated bodies the electro-cautery, applied by means of the point, knife, or snare electrode, is the most convenient agent, although chromic acid, carefully used, will suffice. One of the best methods is to employ a rather heavy point-electrode having its end slightly "curved on the flat" toward the side to be cauterized, and to draw this, in one application, three or four times, at a little more than cherry-red heat, through approximately one inch of the length of the turbinated body, passing each time through the same line until the soft tissue is penetrated to the bony base. From three to six treatments, in different lines on each of the lower turbinated bodies, may be required. Fewer suffice for the middle bodies.

Septal excrescences are removed by the nasal saw, chisel, or burr and trephine drills propelled by the surgical engine or electrical motor. The latter apparatus is more useful for drilling away projecting edges and corners after the use of the saw than for execution of the entire operation. A large variety of nasal saws is necessary in order best to conform to individual cases.

If the septum is seriously deflected it may be necessary to correct it.

Adenoid vegetations of the naso-pharynx must be cleared away.

While this work is progressing such polypi as can be reached should be removed, and others as rapidly as access is gained. This is done by the

galvano-cautery snare, the cold snare, or fine polypus forceps, whichever seems best adapted to the individual polyp.

All operating is done under the local anæsthesia, and *retraction of tissues* produced by cocaine applied by spray in solution not to exceed 5 per cent., and on cotton not to exceed 2 per cent., and operating must cease as soon as hæmorrhage obscures the view.

But the real success of the treatment, after having gained access to the polypi, consists in tracing them to their points of attachment and in thoroughly cauterizing these so-called roots; if not at the same sitting, then at the next, remembering meanwhile the exact spot. Knowing the *hiatus semilunaris* to be a favorite point of origin, those polypi which proceed from beneath the middle turbinated body should be followed up by insinuating a fine electrode slightly curved on the flat to this point, and those which spring from the superior meatus posteriorly must be reached by a properly curved point-electrode introduced through the mouth and naso-pharynx, always under the best illumination.

The latter procedure is by far the most delicate part of the operation, and it is often necessary to tie the velum forward or to use a self-retaining palate retractor.

No. 70 Monroe St., Chicago.

THE IMPORTANCE OF LOCAL TREATMENT IN SYPHILIS.¹

Read before the Section on Dermatology and Syphilography, at the Thirty-ninth Annual Meeting of the American Medical Association, May, 1888.

BY JOSEPH ZEISLER, M.D.,

OF CHICAGO.

PROFESSOR OF GENITO-URINARY AND SKIN DISEASES, CHICAGO POST-GRADUATE MEDICAL SCHOOL; MEMBER OF THE AMERICAN DERMATOLOGICAL ASSOCIATION.

There are few diseases like syphilis, for which our therapeutical actions are so well defined, for which we possess specific remedies, upon whose never-failing effect we count with nearly absolute certainty; yet nowhere is the Latin phrase equally true: *duo si faciunt idem, non semper est idem*. The where, when, and how to use those two chief agents, mercury and iodine, seems to be to many a *terra incognita*, and the prescribing of the mixed treatment forms the beginning and the end of their fight against that dread disease, in whatever phase it may be, whether it has attacked the skin only or other more important organs. The result of this *laissez aller* is often a very sad one, and many a perforated septum or palate, or even the loss of a considerable part of the nose is due to the fact that local treatment has not been given a proper place in the management of that case. This may sound somewhat hard, but I speak from ex-

¹ This paper was mislaid by the Section officers into whose hands it came. Hence its late appearance.

perience, and having observed a few such cases of late which impressed me very strongly, I have chosen this theme for my present paper. There is nothing especially new to be said in regard to this subject, at least not for those engaged in the special line of dermatology and syphilis, but it seems to me to be not at all superfluous to call the attention of the practitioners at large to the important rôle which local treatment plays in the management of syphilis, as the text-books usually touch this question in a rather superficial manner. In laying special stress upon local applications, I hope I shall not be understood as underestimating the necessity of constitutional treatment in every single case; this, of course, is a *conditio sine qua non*.

There is in nearly every stage of syphilis more or less opportunity for the successful employment of local remedies, while in some cases, mostly such showing tertiary forms, they are of the greatest importance.

In regard to the primary indurated sore, the majority of physicians to-day refrain from giving constitutional treatment and employ various local measures to secure a speedy cicatrization. The question of excision might well be discussed here, should it not abstract us too much from our theme; there can little be argued against it, when the localization allows it, as healing often takes place by primary intention. As regards its preventive effect opinions are divided. Believing the induration to be the sign of general infection, I fail to see how excision can abort the disease, and the reports of seemingly successful operations are surely capable of different explanations. In the management of hard chancre, it is always desirable to make the induration disappear as quickly as possible. For this end I have found the mercurial plaster a very valuable agent; it constitutes the simplest, cleanest, most practicable and efficacious treatment of the primary sore. As reference will again be made to this plaster, I wish to say that I always use that prepared and spread by Seabury and Johnson, which in every respect proved satisfactory.

After secondary symptoms have appeared, there is a very useful field for local applications. In selecting the plan of a general treatment I have always given preference to the time-honored frictions, which, in spite of all objections, still form the most reliable way to treat the earlier manifestations of syphilis. Besides their constitutional effect they have an undoubted local influence upon the cutaneous eruptions, causing them to vanish usually very rapidly. Patients in private practice will mostly desire before all to have the visible manifestations, as on forehead and hands, disappear as soon as possible; for this purpose a 10 to 20 per cent. ointment of the white precipitate will often work like a charm, and this result will always be highly appreciated by pa-

tients in the better walks of life. Still, the papular syphilides on the palms and soles, the so-called psoriasis specifica, will occasionally prove very obstinate and will call for more energetic measures. Thus chrysarobin has been recommended by Reumont² and by Mosengeil,³ who have successfully used it as an ointment of 10 to 20 per cent. strength. Sigmund⁴ speaks very highly of a 1 to 2 per cent. solution of sublimate in collodion. This should be painted once or twice daily on the infiltrated plaques; fissured places, of course, should not be touched by it, these are best covered with strips of the gray plaster. Gilles de la Tourette⁵ has found warm local baths with an addition of 1 part each of sublimate and of chlorate of ammonia to 2,000 parts of water, as very efficacious for that trouble. Papules appearing on mucous membranes, mostly in the throat, will readily heal when touched daily with nitrate of silver in strong solution or in substance, and under the use of an astringent gargle.

Of far more importance are topical applications for moist papules or condylomata lata, as these not only are the cause of much annoyance and discomfort to the patient, but also form one of the most common sources of syphilitic infection. As they are so easily reproduced by coaptation of opposing surfaces of the skin, as, for instance, in the genito-crural or anal folds, it is before all necessary to keep such places carefully separated by the application of absorbent cotton or gauze, and to scrupulously remove the fetid secretion by frequent cleansing with diluted sublimate solutions. For the removal of those characteristic vegetations developing so often on such places different caustic pastes have been recommended, but their application is attended with a great deal of pain. I usually prefer the cauterization with the silver stick, after previously anesthetizing the parts by a strong cocaine solution. Moist papules on the corners of the mouth or between the toes are often very painful, but they heal readily when touched with nitrate of silver and covered subsequently with mercurial plaster.

There is rarely occasion to act against the swelling of lymphatic glands. I lately treated a young man in whom a group of infiltrated glands, situated between the lower jaw and the mastoid process, caused a constant pain and great difficulty in swallowing. An ointment containing iodine, iodide of potassium and ichthyol reduced the swelling in two days and brought perfect relief. For suppurating bubos surgical interference will, of course, be necessary.

During any form of treatment with mercurial preparations the mouth will always require attention, as the saliva soon becomes impregnated with the drug and is the direct cause of mercurial stom-

atitis. The most diligent care of the teeth and gums, abstinence from tobacco and irritant substances, and the frequent use of an astringent mouth-wash will greatly aid to delay this incident. Brockhart⁶ recommends a solution of 5 to 10 parts of tannic acid in 20 parts of glycerine to 80 parts of water for this purpose. The gums may sometimes become so tender as to make mastication very painful and to necessitate an interruption of the administration of mercury. To overcome this the same author has suggested the use of a 10 per cent. cocaine solution, to be painted on the delicate parts a few minutes before meals.⁷

We have thus far seen that, during the earlier manifestations of syphilis, there are many indications for local treatment. In the later stages of the disease it becomes often imperative, and Hutchinson, who regards tertiary symptoms as mere local sequelæ, has gone so far as saying that only local remedies will lead to success in treating them, whereas constitutional treatment is of minor value.⁸ There is much truth in this. While general treatment, especially the use of iodides, is certainly capable of removing many of the symptoms incidental to the so-called tertiary period, it will be entirely unable to arrest the destruction which, for instance, serpiginous ulcers produce on the skin and mucous membranes, and here it is where local treatment is followed by the most brilliant results. Allow me to illustrate this.

Anna S., 16 years old, was brought to my office the 17th of December, 1887, through the kindness of Dr. C. Fenger, who in an accompanying letter asked me to conduct the medical treatment, while he later on should do the surgical part of the work. Without going into the details of the history of this case, which, from its aspect (general cachexia, Hutchinsonian formation of teeth, etc.), and from the anamnesis, had to be regarded as due to hereditary causes, I shall briefly state that the whole upper lip and both alæ nasi were the seat of those characteristic ulcerations resulting from the breaking down of gummatous neoplasms. The cartilaginous part of the septum was perfectly destroyed, only the small anterior cutaneous bridge remaining; accordingly the dorsum was depressed as a result of the defect. The anterior portion of the nose, where not ulcerated, presented that peculiar livid tint, and it seemed only too natural that the necessity of a rhinoplastic operation in the near future was suggested to Dr. Fenger. The affection was said to have begun with a peculiar eruption on the nose about one and one-half year ago, which was followed by a swelling of the upper lip. For the last six months she had been under the care of a prominent specialist for the diseases of the throat and nose. *Sapienti sat!*

I immediately began energetic local treatment

by using the silver stick very liberally every second day. The patient was directed to clean the sores twice daily with a 1 per cent. sublimate solution, and to cover the same in the meantime constantly with the adhesive gray plaster. Iodide of potassium in daily doses of 2.00 was prescribed for internal use. The effect of this treatment was all I could hope for; within ten days the ulcerations were completely healed, a very smooth cicatrization having taken place, and the shape of the nose was preserved. By inserting two small rubber tubes the contraction of the scar tissues around the opening of the nose was prevented. The patient, of course, was only too glad to be saved the trouble of a plastic operation.

Cases like this are, fortunately, in our days not very common; but they must not happen at all, and to let the destruction go on undisturbed until an important organ is endangered, borders on criminal negligence or ignorance.

I have on record the notes of a case where extended, deep syphilitic ulcerations had existed and spread on the scalp of a man for over two years when I began to treat him, in December, 1886, after the principles just mentioned, and in less than two weeks perfect cicatrization had taken place, the patient remaining well ever since.

To the kindness of Dr. M. Mannheimer, of Chicago, I owe a very interesting case of a woman about 30 years old, whom I treated in the winter of 1884. She had been infected about 1½ yrs. ago by her husband, who confessed to having had an indurated chancre, but otherwise did not remember to have suffered from any symptoms of constitutional lues. The woman herself knew nothing of having had a primary sore, nor the usual secondary manifestations, but the first thing she noticed was the appearance, judging from her description, of a generalized rupia about a year ago, which soon became ulcerated. When I first saw her, she was simply covered with those horse-shoe formed sores; the whole scalp was one ulcerated surface, producing an unbearable smell. The back of the right hand was nearly perfectly destroyed, and about sixty more ulcers, from the size of a penny to that of the palm of a hand, were present on the rest of the body. The forehead, nose and chin were the seat of an ecthyma eruption. The patient suffered a great deal, and was hardly able to find comfort in any position. I ordered iodide of potassium 2.00 pro die in solution, a warm bath medicated by 10.00 of sublimate daily for an hour, emplastrum hydrargyri as a local dressing, and white precipitate salve for the face, while the scalp, for the first few days, was to be saturated with salicylated olive oil to facilitate the removal of crusts and detritus, and afterwards washed daily with sublimate soap and anointed with the mercurial salve. The sores were touched every third day with nitrate of silver. Healing soon began to take place on some of the smaller ulcers,

⁶ Monatshefte f. prakt. Dermatologie, No. 8, 1885.

⁷ Ibid., No. 2, 1886.

⁸ Syphilis, Discussion, London Pathological Soc., 1876.

and after a little over two weeks the patient was completely cured, and only continued to take the iodide for some time. She has remained well ever since.

I could cite quite a number of other observations just as striking, but these few examples may be sufficient to show the efficiency of local treatment in these graver forms of cutaneous syphilis.

I wish to add only one word with reference to the cauterization by nitrate of silver, which I regard as a very essential part of the treatment. Its use was formerly accompanied by a great deal of pain; now I always employ previously a 5 to 10 per cent. solution of cocaine for a few minutes, by which it is possible to make that operation without the least objection on the part of the patient.

Ulcerating syphilides may occasionally become phagedenic and resist all kinds of treatment. For such cases Spillmann⁹ has recommended the free use of Volkmann's sharp spoon, subsequent application of Paquelin's cautery and dressing with sublimate solution. I have so far had no occasion to resort to these radical measures.

It would be beyond the scope of this merely suggestive paper to speak at length about the treatment of syphilitic affections of the tongue, the nose, throat and larynx, the eye and ear, the bones, etc.; this must be left to those who make these organs their special study. What has been said in regard to the skin applies still more to them. When necrotic bones are the cause of a chronic ozæna, when a gumma is about to destroy an eyelid, when exfoliative perichondritis in the larynx may at any moment endanger the life of a patient, there is no time to wait for the effect of internal treatment; this will certainly in many respects be a valuable adjuvant, but only *local* applications will be able to arrest the destructive processes in those important organs.

MEDICAL PROGRESS.

FORTY-TWO CASES OF INTUBATION.—DR. F. K. PRIEST reports: In a series of 266 cases admitted to the Willard Parker Hospital, intubation was performed for the relief of laryngeal stenosis, in 42, or a little over 22 per cent. of that number, with a percentage of recoveries of 26.19. The majority of these cases were of undoubted diphtheria, with well-marked symptoms of laryngeal stenosis, at the time of admission, while many of them had been without proper care or medical treatment and well-advanced in the last stages of septicæmia, the operation being performed merely for the relief of the stenosis, with no hope of ultimate recovery.

Of the 42 cases 8 were cases of diphtheria com-

plicating or accompanying other contagious diseases, as follows: 1 case of measles and diphtheritic conjunctivitis; 1 of varicella; and 6 of scarlet fever. In 35 of the 42 cases membrane was present in the throat or anterior nares, or coughed out either before or after the introduction of the tube; in the 7 remaining cases, the presence of membrane was not detected at any time during the course of the disease, although there was more or less swelling of the cervical glands with discharge from the nostrils. Only one of the seven recovered.

On admission in 29 cases, the symptoms of laryngeal stenosis were well advanced, 25 of this number being unquestionably diphtheria, and one case in which the presence of membrane could not be detected, a large piece was coughed out during the introduction of the tube. In 5 cases there was a hoarse, croupy cough without dyspnoea, and in 8 the laryngeal symptoms developed after admission. In all cases where the character of the dyspnoea and the general condition of the patient permitted of the delay, intubation was not resorted to until other means for the relief of the stenosis had been tried and failed to give more than temporary relief.

In 3 cases only, where the urine could be obtained, albumin was not found on examination, several dying from acute nephritis with suppression of urine, as occurred once five days after the removal of the tube, all local evidences of diphtheria having disappeared at the time. This one has been included in the list of fatal cases, as the patient was not discharged from the hospital, although it might be considered as a successful case of intubation.

In those cases that recovered, the average time the tube remained in the larynx was 6½ days. No definite rule, however, was followed as to the time of removal. In cases that were progressing favorably the tube was left in position until the membrane had disappeared from the throat and nose and the fever had subsided. The tube was removed in one case on the fifth day, the membrane being still present on the tonsils; on account of violent and persistent coughing and vomiting after taking fluids, the urine was also scanty, high colored, nearly three-fourths albumin; after which the cough was less troublesome, vomiting ceased, and the child took plenty of fluids; although the breathing was somewhat stridulous there was no return of the dyspnoea.

Coughing after drinking was a constant symptom and, in several cases, it was severe enough to induce vomiting. The above case was the only one, however, in which this symptom was severe or constant enough to seriously interfere with the ordinary feeding or treatment. The most troublesome complication, and one that in several cases was productive of very alarming symptoms, was from the collection of mucus in

⁹ Ann. de Derm. and Syphilogr., 1885, p. 712.

the throat and consequent obstruction of the tube. This was found especially apt to occur in very young children during the night or early hours of the morning, the child being unable to expel, by coughing, the mucus that gathered in the throat during sleep; as a result the respirations became labored and, if not relieved, gave rise to intense dyspnea, interfering with the circulation, and, in fact, all the symptoms of stenosis of the larynx. For the relief of this symptom syrup of ipecac, in doses sufficient to produce vomiting, was given with good results, the act of vomiting expelling the mucus, and relieving the dyspnea without disturbing the tube. Emesis was thus induced several times in one case, which afterward recovered.

The removal of the tube was always followed by more or less stridulous breathing, lasting from a few minutes to several hours, and in several cases by dyspnea coming on in a few seconds or minutes and rapidly becoming alarmingly stenoitic, necessitating the immediate reintroduction of the tube. In a child one year of age, the tube was coughed out on the fifth day, symptoms of stenosis suddenly appeared and the patient became unconscious; tracheotomy was immediately performed. The child revived and was apparently as well as before the tube was removed, but died quietly 8½ hours after the operation.

In 3 cases, the removal of the tube was followed by symptoms that seemed to point to ulceration of the larynx or trachea, and in one in which a partial autopsy was obtained such was found to be the case.

In 3 cases of severe diphtheria, with nephritis, dying from the effect of the septic poisoning, in which slight dyspnea was present, the tube was removed and found to be nearly filled with thick mucus and cheesy material, the patients breathing easily and naturally after its removal, without any return of the dyspnea.

The average age was 2 years and 11 months; youngest 9 months, oldest 7 years. In 25 cases admitted with diphtheria in which a fairly accurate history was obtained, the day of the disease varied from the second to the ninth, the average being the fourth. Swelling of the glands of the neck was marked in 28, slight in 11, and absent in 3 cases.

Discharge from the nostrils was slight in 6, marked in 8, sanguineous in 11, and absent in 7 cases, although membrane was present in the anterior nares in only 13. When present in the throat the membrane was confined to the tonsils in 14, to the soft palate in 1, to the tonsils and soft palate in 8, and to the tonsils, soft palate, and pharynx in 9 cases.

In the majority of cases it was found very difficult to obtain a clear history as to the time of the first appearance of the laryngeal symptoms, *i.e.*, the croupy cough.

In 25 cases the time from the first appearance of the laryngeal symptoms to the introduction of the tube varied from 24 hours to 8 days, the average being about 4 days.—*Medical Record*, February 23, 1889.

PHENYL-PROPIONIC ACID IN PHTHISIS.—DR. C. THEODORE WILLIAMS, in a paper on "New Antiseptics in Phthisis," says of this substance:

Phenyl-propionic acid ($C_9H_{10}O_2$) is one of the numerous derivatives of coal-tar, and consists of acicular crystals of reddish-white color, insoluble in water, but dissolving in spirit (1 in 6), and giving a feeble acid reaction on testing. A saturated alcoholic solution was made and diluted with water, with which, however, it was found not to mix well, 10 minims requiring an ounce of water to keep it in suspension. When so dissolved it had a sour aromatic taste, not at all unpleasant, with a decided aroma, which often pervaded the air of the ward. The alcoholic solution was administered in 10-minim doses with an ounce of water, and was generally increased to 20 minims in 2 ozs. of water three times a day. This was the largest dose given. Twenty hospital patients were selected for the treatment, 6 males and 14 females. The ages of the males varied from 20 to 45, and that of the females from 14 to 41, the average age of the latter being 20.

Duration of Disease.—The cases were for the most part those of chronic phthisis, nine of them having been ill for at least two years, and some for longer periods, though in the rest the symptoms dated a few months back. There were the usual symptoms of phthisis, including much wasting and night sweats. One patient was a case of scrofulous phthisis; the rest were of the ordinary chronic tuberculous type. Pyrexia was present to a greater or less extent in four patients.

State of the Lungs.—Nine were cases of tuberculization, 6 of one lung, the right being the one attacked in 4 and the left in 2; 3 were cases of double affection, both upper lobes being the seat of tubercle. Cavities were present in 11 cases, more than half the whole number, 3 were single cavity cases, 1 with tinkling cavernous sounds, and the opposite lung free from disease, 1 a double cavity case, *i.e.*, with a cavity in each lung. The remaining 7 were cases of a cavity in one lung and tuberculization of the upper lobe of the opposite one. This gives a total of 11 cases of double affection against 9 of single affection. The case of scrofulous phthisis presented consolidation of both upper lobes with no cavity; there was considerable enlargement of the cervical glands. In 14 cases the sputum was examined for tubercle bacilli, and in 13 they were detected in varying abundance.

It will be seen that, judging by, 1, the large proportion of cavity cases; and 2, of double affection; and 3, the inclusion of some pyrexial pa-

tients, they were not very favorable specimens, and many belonged to the category of unfavorable cases.

The patients took the phenyl-propionic acid for periods varying from 28 to 85 days, the average being 46.7 days. As a rule it caused neither nausea, vomiting nor anorexia, except in 2 cases, in each of which the nausea was overcome by further diluting the medicine with water. The peculiar odor could not be detected in either the perspiration, the urine, or the feces, in all of which secretions it was duly searched for. The patients took no other medicine, except alterative purgatives when necessary.

General Results.—Thirteen improved, 4 remained in a stationary condition, and 3 became worse. The improvement consisted chiefly in gain of appetite, strength and color (one interesting point being that in the pyrexial cases the phenyl-propionic acid exercised no influence on the temperature-curve); 14 gained weight, varying from $\frac{1}{2}$ lb. to 5 lbs.; 4 lost weight, and 2 neither gained nor lost; the largest gain was 5 $\frac{3}{4}$ lbs.; the greatest loss 7 lbs. Of the 4 pyrexial patients, 2 lost weight; in 1 it was stationary, and 1 gained weight. The "first-stagers," or cases of tuberculization, did not seem to improve as much as the cavity cases, for while, out of 9 first-stagers, 5 improved, 3 remained stationary and 1 deteriorated; out of 11 third-stagers 8 improved, 1 remained stationary, and 2 became worse. The double cavity case improved greatly, and gained 3 lbs. in weight. From this we should be inclined to infer that phenyl-propionic acid exercises more influence on suppuration than on tuberculization.

Local Results.—In 5 patients the condition of the lung showed a distinct improvement, 3 being cases of tuberculization, and 2 cases of cavity with disease of the opposite lung; in 9 no change in the lungs could be detected after the treatment, and in 6 there was either advance or extension of disease, or both. These results contrast unfavorably with the general ones, and confirm a common experience in pulmonary disease, that general improvement is far easier to obtain than local quiescence. The medicine was not observed to diminish the amount of expectoration, or specially to reduce the cough, but decided increase of appetite, and gain of weight, color and vigor were noted in the cases "improved."—*The Practitioner*, February, 1889.

A NEW FORM OF RECTAL MEDICATION.—H. F. MEIER suggests, for the rectal administration of glycerine, a suppository, prepared by the simple addition or the incorporation of a special kind of soap. This soap, characterized by extreme hardness, known as stearine soap, has the property of imparting to the glycerine in which it is dissolved the requisite degree of firmness. These

suppositories, from the nature of the composition employed, offer the medicinal ingredients in as compact a form as possible, containing as high as 95 per cent. of glycerine. In this respect they offer a decided contrast to the form prepared by filling hollow cones of cocoa butter, and which, from the nature of the material, are of an uncomfortable size. The hygroscopic nature of the glycerine requires that reasonable precautions be taken to preserve the suppositories in a dry atmosphere, in order to prevent the accumulation of moisture on their surface and consequent dilution of part of the glycerine, with possible loss of activity.

The form adopted is a double-pointed cone. The closing of both sphincter muscles around it results in an upward movement, undoubtedly assisted by the impetus originally given. It has been found that this form offers the least amount of obstruction to such reflex peristalsis. Experience has shown that perfect solution is not indispensable to their activity, but that they are capable of provoking a laxative effect without a noticeable loss of substance. That the glycerine, however, exudes or escapes, so as to exert an effect, can be admirably shown by suspending a suppository at the surface of a test tube filled with water. This is accomplished by simply running a pin through the upper end of the suppository, the ends of the pin projecting over the tube. The glycerine can now be seen to escape and its rapid downward flow observed. These suppositories have been used extensively and with quite uniformly beneficial results, both in this country and in Europe. While it is possible to prepare a suppository which would be entirely soluble or nearly so, success has not yet attended the manufacture on a large scale of such with regard either to economy or safety, that is, as far as their keeping qualities are concerned. A suppository which, while possessing this apparently desirable feature of solubility, melts below the average temperature of the body, 98° F., cannot at the same time be either adapted or expected to withstand the vicissitudes of climate to which it would inevitably be exposed in different sections of a large country.

Cases have been met with in practice, in which these suppositories were not applicable; indeed, in which the introduction of any foreign substance except clysters is contraindicated. Considered from a physiological standpoint, the action of these suppositories would naturally be confined to the rectum and usually the lower part of the great intestine. Where obstruction exists in the intestines too far removed from the tracts just named, other means must necessarily be adopted. Frequently certain febrile or inflammatory conditions of the intestinal tract would alone preclude their use. Such contraindications are self-evident to the observing physician. While these suppositories have in many cases decided advantages over

like contrivances prepared from gelatin, unfortunately their range of application is limited. This results from the chemical nature of the agent employed to solidify the glycerine. It will be evident from these considerations that many medicinal agents, which it would be desirable to administer in the form of suppositories, would be incompatible with the base employed, while others not affecting the soap with resulting decomposition, can be employed to better advantage in this way than when cloaked with an excipient or carrier of a fatty nature.—*Druggist's Bulletin*, February, 1889.

CITRATE OF CAFFEINE IN ECLAMPSIA.—B. CORNEY reports a case of a woman, æt. 23, who gave birth to an undersized but full-time child at 7 A.M., August 21st, after an easy labor of three hours. About noon headache came on; at 9 P.M. vomiting took place, and at 11 P.M. convulsions set in, lasting, with intermissions, ten hours. The bromides, hyoscyanus, chloral hydrate, and chloroform did not seem to have much effect. The patient remained in a deep stupor for three nights, and the two intervening days. There was slight fever, a weak pulse varying from 80 to 132, great cyanosis, incontinence of urine, and left hemiplegia. As the vital powers appeared to be rapidly failing, it was necessary to take some decisive step. Corney objected to alcohol, because of the imperfect aëration of the blood that was going on, as evinced by the cyanosis. He was uncertain how much of the stupor and cardiac weakness was due to the disease, and how much to the bromide and chloral. Caffeine suggested itself, and he immediately injected grs. iij of the citrate dissolved with grs. iiss of sodium salicylate in ℥ x of distilled water. This was followed in an hour by six grains more given by mouth, and two grains every two hours afterwards for six doses. Some general improvement took place, the pulse bettered, and the attacks of lividity ceased. The paralytic symptoms diminished in degree, and towards dawn on the 24th signs of returning consciousness were observed. The caffeine was continued for two days, and from this time the patient made a steady recovery. A week later the only remaining abnormalities were a certain degree of muscular weakness and debility.—*Practitioner*, Feb., 1889.

PERMANENT SLOW PULSE AND URÆMIA.—Referring to those cases of permanent slow pulse (28 to 30 per minute), in which Charcot has said a medullary lesion must exist, DEBOVE has, in just such a case, examined the medulla and found no lesion. He recently had under his care a man of 80 years, who had been seized, during a course of dyspnoëic attacks, with syncope and epileptiform attacks. His pulse was 32. His heart and lungs seemed normal. He was passing about 600

cc. of urine a day, which contained from 7 to 8 grams of urea and no albumin. Milk diet caused diuresis, and an increase of urea up to 20.5 grams a day and the dyspnoëa disappeared, the slowing of the pulse continuing unchanged. Gingeot has seen the pulse rise from 32 to 40 on the accession of acute bronchitis in a similar case, while the axillary temperature was 102°.—*Le Practicien*, Dec. 10, 1888.

MENTHOL IN PRURITIC AFFECTIONS.—Menthol is recommended by SAALFELD (*Deutsche Med. Wochenschrift*, No. 46, 1888), as exceedingly beneficial in cases of pruritis of various kinds. He prescribes it either as a wash or as a salve, the formulæ being:

I. Menthol 1.5-2.5 grams
Spirit vin. rect. 50.0 "

and

II. Menthol 2.5
Ol. Olivarium 7.5-10
Lanolin. ad. 50.0

Both preparations have done him excellent service in uriticaria, pruritus cutaneous, and pruritus senilis.

A case of intolerable itching consecutive to otherwise successfully treated scabies was perfectly cured by applications of the following ointment:

Menthol 2.5 grams
Bals. Peruv. 5.0 "
Ungt. Wilson (Ung. Zn. benz.)
Lanolin, pur. aa ad. 50.0 "
N. f. ungt.

Menthol as a 10 to 15 per cent. ointment proved likewise very valuable in chronic eczema, even in quite inveterate cases.

SUPPOSITORIES FOR CYSTITIS.—

R. Iodoform 134 grains.
Extr. of hyoscyanus 1 grain.
Cocoa-butter 45 grains. ㄹ

Make one suppository and introduce high up into the rectum.

The bladder should be washed morning and evening with lukewarm water. If there be any urethral irritation, a pill containing 134 grains of terpin should also be taken morning and evening. *Journal de Médecine*, January 6, 1889.

TO ABORT ACUTE BRONCHITIS DR. H. C. WOOD recommends

Potass. citrat. ʒi
Syr. ipecac ʒi
Succus limonis ʒi
Aque ʒiij

S. Two teaspoonfuls every two hours.

WARMING MEDICINES BEFORE ADMINISTRATION.—LEWIN recommends the warming of medicines before administering, and of subcutaneous solutions as well. The absorption, he points out, is much quicker and the doses necessarily smaller. *The Medical Age*, February 29, 1889.

CHICAGO, ILLINOIS.

All members of the Association should send their Annual *Dues* to the *Treasurer*, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

LONDON OFFICE, 57 AND 59 LUDGATE HILL.

SATURDAY, MARCH 16, 1889.

IS THE ANTIPYRIN CRAZE HARMLESS?

The number of new drugs constantly recommended to the therapist is bewildering. The fertility of the synthetic chemists of Germany seems as exhaustless as the coal beds whence they derive their material. Yet it is questionable whether or not the practice of medicine is benefited by this multiplication of remedies. Paraldehyde, hypnone, urethan and now sulfonal, have all in turn been vaunted for their remarkable hypnotic virtues, and yet our old stand-bys, such as chloral hydrate, continue to maintain their supremacy. Some of the most recent testimony on this point has come from no less an authority than Dr. Huchard, whose conclusions were summarized in our letter from Paris in THE JOURNAL of February 23. He has tried sulfonal and found it inert in phthisis, heart disease, subacute articular rheumatism, neuralgia, etc., and therefore believes that its special sphere of action must be in nervous sleeplessness. In his experience it is not free from serious drawbacks, since it may produce an altogether too prolonged sleep and be followed by nausea, dizziness, a feeling of weariness amounting to great lassitude. It is likely, therefore, that none of these hypnotics will wholly supersede chloral.

But there is one group of coal-tar derivatives that has sprung into widespread popularity, and for which the demand seems not to abate. These are the antipyretics, and at their head stands antipyrin. Its sphere of action is wide, but our knowledge of its utility is almost entirely empir-

ical. In addition to powerfully depressing febrile temperatures, it was found to possess remarkable influence over pain, particularly all forms of neuralgia. The result is, that not only do physicians prescribe it for headache, neuralgia, myalgia and the like, and throw it into the rectum to allay the pains of parturition and dysmenorrhœa, but druggists dispense it without requiring a prescription, and the laity keep it on hand, it might almost be said, *on tap*. Is this state of things desirable? It certainly is not, so far as the people and druggists are concerned, and in the case of physicians it may be fairly asked if such empiricism is not calculated to beget loose methods. The ultimate duty of the physician should be to heal by removing the cause, wherever possible, not to rest content with affording temporary relief only. Yet, with a means at hand of removing pain less injurious than opium, is it not a temptation to limit attention to the treatment of symptoms? If, nevertheless, it is urged that such use of drugs is not only legitimate, but actually good policy so long as they appear to be harmless, the query may be made in response, Is antipyrin so harmless as it seems? "Ay, there's the rub;" as yet but very little is known as to the effect of this remedy upon the physiological processes of the human body. A few facts, however, appear to be established. MM. Lépine and Porteret (*Comptes Rendus*, Nos. cvi and cviii), have found that when it is administered to guinea-pigs and when the fresh liver is immersed in a solution of antipyrin, the conversion of glycogen into sugar in the liver is hindered. To be sure, proportionately larger doses were administered in their experimentation than would be given therapeutically; yet, the prolonged or daily ingestion of this drug might produce a similar result in man. Accordingly, on this hypothesis, M. Germain Sée has employed it in diabetes mellitus and actually found a diminution in the amount of sugar excreted. Since, then, this function of the liver is thus limited, is it too much to assume that this organ may have its other functions deranged likewise? particularly, its conversion of nitrogenous matters of the food into urea. Furthermore, Sawadowski (*Centralbl. f. die Medicin. Wissensch.*, 1888, Nos. 8, 9 and 10), in experiments on dogs, discovered in animals with fever an increase in the amount of nitrogenous materials excreted, also that, in the strength of 2 per cent., a solution of antipyrin destroyed the red blood corpuscles,

and in the strength of 3 to 5 per cent. rendered the blood lakey. He furthermore found that, in large doses, it produced convulsions, and came to the conclusion that the emesis occasioned by it was because of action on the central nervous system.

It may be urged that the increased excretion of the products of tissue-waste produced by antipyrin in febrile dogs indicates a better elimination and not necessarily any actual augmentation of retrograde tissue change. On the other hand, since the febrile condition occasions a greater than normal destruction of tissue, it is probable that this process is really helped along by antipyrin. Indeed, there are facts drawn from *post mortem* observation that bear this out. We quote with reference to this point, from Prof. W. H. Porter's paper (The Etiology and Pathology of increased body heat in relation to disease and the use of Antipyretics), read last June before the Ontario Medical Association. Speaking of all the members of this group to which antipyrin belongs, he says: "Experimental study, however, shows that in large doses they produce a rapid and marked parenchymatous metamorphosis of the liver and kidneys, which is followed by albumen and casts in the urine. They are also thought to have direct depressing effect upon the medullary and spinal centres. This being true, is not their antipyretic action due to their causing a further increase in the functional and organic metamorphosis of the protoplasmic elements of the body, which disturbs still more the physiological processes of the liver, kidneys, and excretory organs, and thus cause a greater accumulation of the effete and toxic matter in the blood, until accumulation becomes so large that a state of general depression is produced, which throws the system into a condition strongly simulating that known as collapse, during which the temperature falls?" Further on occur these sentences: "Pathologically we find at the present time more marked and destructive parenchymatous changes in the liver and kidneys than was the case before the introduction and use of this group. In many instances the examination of the liver and kidneys has revealed a condition of granular and fatty metamorphosis equally as bad as that found in acute yellow atrophy of the liver, or in connection with acute phosphorus poisoning."

The analgesic qualities of antipyrin have led to

its employment in cases of labor, and the reports of its influence over these pains are quite enthusiastic. But associated with this effect appears to be that of lessening the secretion of milk (*vide Medical News*, Dec. 8, 1888, a paper by T. Haven Ross, M.D.).

Whether these and other effects of this group of remedies are substantiated or not, there is ample clinical evidence that these are dangerous agents to trifle with. Hence, would it not be wise to exercise more caution in the administration of these powerful drugs than at present appears to prevail? Is it not high time that somebody called a halt in this present display of dangerous, though tempting empiricism? Can this antipyrin craze be said to be harmless? We think not.

ANÆSTHETICS IN DENTAL PRACTICE.

IN THE JOURNAL of March 2 we noticed editorially a case of death from chloroform in a dentist's chair. DR. J. C. REEVE, of Dayton, Ohio, has kindly sent us the October, 1888, number of the *Dental Register*, containing an article on "Anæsthetics in Dental Practice" from his pen, which, on the subject of anæsthetics, is one of the ablest in the profession. Dr. Reeve says: "There is no professional duty I perform so unwillingly as that of administering an anæsthetic for dental purposes, no fee that I consider so hardly earned as that which I receive for this service. At the same time I am frequently giving anæsthetics for general surgical purposes without hesitation and without undue anxiety." Again he says: "Are anæsthetics more dangerous in dental practice than in general surgery? The answer must be unqualifiedly in the affirmative. Without attempting to collect statistics take only those of the Royal Medico-Chirurgical Society and those of Sanson.¹ The one gives 8 cases of death under tooth-drawing out of 100 of all operations, and the other 12 out of 107. Here then is nearly 10 per cent. of all the deaths occurring in dental operations. But this statement alone gives no just idea of the relative mortality. This could only be accurately ascertained if the total number of administrations in all surgical operations was known. Certainly anæsthetics are administered for general surgical

¹ On Chloroform, London, 1865, p. 69.

purposes hundreds of times for once in dental practice, and if so, then the relative number of deaths under tooth-drawing is enormously large. The causes of the high rate of mortality during this particular operation are not far to seek. I do not believe that the entrance of blood into the air-passage is very important. Several deaths, however, have been caused by an extracted tooth falling into the larynx, without doubt due to the position of the patient. Anæsthetics should never be administered unless the patient be recumbent. This is not, however, in my opinion, a very potent factor, and was fully considered in the paper. Another is the particular nerve involved in the dental operation, the acute pain caused by injuries to it, and the powerful effect of sudden impressions upon its branches upon the great and vital processes of respiration and circulation. By sudden impressions upon this nerve more than any other, is that inhibition of the heart's action brought about which is sudden death. Far more important than all, however, is the fact that the induction of anæsthesia for tooth-drawing is likely to be incomplete, and will pretty certainly be so if the operator is also the administrator. Now it is a positive doctrine of the highest and latest authorities that such reflex actions as above given are increased under chloroform, that a state of partial anæsthesia is therefore one of especial danger, and especially so if the pain produced is at once sudden and sharp.² It is gratifying, therefore, to see that this source of danger is fully recognized by the author of the paper, although it is not emphasized as it deserves to be. There is no more seductive procedure than to give a few whiffs of chloroform for the extraction of a tooth; there is no more dangerous practice. If an anæsthetic is given at all, it should be given until the patient is 'off.' There is no plainer doctrine than this connected with the subject."

Dr. Reeve wholly dissents from the doctrine that a full dose of whisky before the administration of the anæsthetic secures safety. There are on record many cases of death from chloroform in which an alcoholic stimulant was given just before the fatal inhalation. In regard to bromide of ethyl, Dr. Reeve thinks it is a dangerous agent, on account of its bad record, and its marked perturbative action on the heart. He

does not know of such objections to the use of nitrous oxide as will justify dentists in resorting to stronger anæsthetics. The objections adduced, he says, "seem but trivial when the tremendous responsibility is considered which the dentist takes upon himself when he proceeds to administer chloroform or ether, when the awful calamity of a sudden death from these agents comes to mind."

It may be said, finally, that when a dentist administers chloroform for the purpose of pulling a tooth, he incurs a responsibility that he has no right to incur.

EDITORIAL NOTES.

THE REMOVAL OF SIMPLE MAMMARY TUMORS by Thomas's operation, says DR. JOHN DAVEY HAYWARD, while manifestly advantageous, seems to be but little known and seldom practiced. The operation consists in making the incision along the curved groove formed below the breast, where it hangs against the thorax (the groove may be marked while the patient is in the erect position); the gland is very readily turned up from the muscle, and the tumor removed from its lower surface by a radial incision. The primary incision is made away from the larger supply-vessels; the weight of the breast obliterates the cavity, and the drainage tube may be removed on the second day; primary union is the rule. Dr. Hayward reports the removal of an adenoma, the size of a small orange, from the upper sternal portion of the gland by this method. It is impossible to find any scar or sign of interference without completely raising the breast.

THE OVARIES AND TUBES AFTER HYSTERECTOMY.—DR. J. GRAMMATIKATI has made a series of experiments, in the laboratory of Professor Lebedeff in St. Petersburg, to determine the fate of the ovaries and tubes after total extirpation of the uterus in guinea-pigs. His results are recorded in *Centralblatt für Gynäkologie*, No. 7, 1889. The guinea-pigs used were, some in normal condition, others in abnormal conditions of life. The abdomen was opened *lege artis*, and the uterus extirpated under the usual precautions in some of the animals; in others the uterus and tubes were removed; in still other cases one cornu only of the uterus was extirpated, with or without the corresponding tube. One ovary was re-

² See Lauder Brunton's *Therapeutics*, and Buxton on *Anæsthetics*, 1888.

moved in all cases, in order to compare it microscopically with the other ovary, after sufficient time had elapsed for changes to take place in the second. From his experiments Grammatikati concludes: 1. After removal of the uterus the ovaries continue to functionate. There is no change in the process of ripening and bursting of the Graafian follicles, nor in the formation of the false corpora lutea. 2. Simultaneous extirpation of the uterus and tubes has no influence on the function of the ovaries. It appears, therefore, that both ovaries should be removed when the uterus is extirpated. Soon after completing his experiments, Grammatikati made an autopsy on a woman upon whom Lebedeff had performed hysterectomy three years before. In the ovaries were found Graafian follicles in all stages of development, and the ovaries showed no trace of atrophy.

AMERICAN PHYSIOLOGICAL SOCIETY; *Prize for Investigations in Regard to some Points in the Physiology of the Nervous System.*—With the wish to promote research in certain departments of Physiology, and to aid in defraying its cost, a member of the American Physiological Society has offered two hundred dollars for the best research or researches bearing on one or more of the subjects stated below, viz: "The rate of transmission of nerve impulses, afferent and efferent, and the duration of reflex and reaction time in the higher animals, especially man; also the conditions, normal and pathological, which alter such rates and times." The competition is limited to residents of North America, and the prize will be awarded for original work done after January 1, 1889. The award will be made by the persons that on October 1, 1890, constitute the Council of the American Physiological Society. In making its award, the Council will take into consideration researches of which printed or legibly written accounts, marked on the outside, "Nerve Physiology Prize," have been received by the then Secretary of the Society before October 1, 1890. To obtain the prize, a research must have a direct bearing on human physiology, and good researches on man will be preferred to similar researches on other animals; but experiments on mammals other than man, if applied to the interpretation of the phenomena of the human body and supplemented by observations on man,

will have weight. Previous publication will not debar a research from the competition, provided the work has been done after January 1, 1889. The council reserves the following rights: to withhold the prize if, in its opinion, no research presented is sufficiently worthy; to award only a part of the prize if, in its belief, a research, though meritorious, does not deserve the whole; to divide the prize between two or more candidates in ratios which seem to it just; and if it think it desirable, to require a competitor to demonstrate his experiments to a committee appointed by the Council. Communications concerning prize should be addressed to H. Newell Martin, Secretary, Johns Hopkins University, Baltimore, Md.

REQUESTS TO WESTERN RESERVE UNIVERSITY.—The Dispensary of the Medical Department of the Western Reserve University, which is now largely maintained by the Hurlbut dispensary fund, consisting of \$10,000 donated by Mr. H. B. Hurlbut, will soon be set on an independent footing. A wealthy local philanthropist has promised an endowment of \$50,000 for the dispensary. Hitherto the work in this department was comparatively limited, but with this additional fund much good work is promised for the future. The Laboratory of the College is now being thoroughly refitted with new and expensive apparatus, and another local capitalist has given the faculty *carte blanche* to buy the best possible instruments wherever they can be purchased.

DEATHS OF CENTENARIANS.—Chesley Heal, born at Westport, Me., on November 16, 1778, died at Searsport, Me., on October 6, 1888, aged almost 110 years. He was a soldier in the War of 1812. It is said that he voted at every election from 1800 to 1880, his first vote having been cast for Thomas Jefferson. He lived an unusually quiet and orderly life, and it is said that he was visited by a physician but once during his long life. On March 1 Mrs. Margaret J. Mitchell, of Cleveland, Ohio, died at the age of 100 years and 2 months. She was born at Georgetown, Me., and lived in Maine until the age of 90 years.

OSSIFYING SARCOMA.—At a recent meeting of the Pathological Society of London, MR. D'ARCY POWER showed a very complete series of specimens of ossifying sarcoma. The case was that of

a girl, æt. 13, who applied for relief on account of a swollen knee, due apparently to tubercular synovitis. The knee rapidly increased in size, and the thigh was amputated in the middle third. Examination of the limb showed a large ossifying sarcoma surrounding the condyles, and extending along the shaft of the bone for almost six inches. A month after the amputation an enlarged gland was removed from the groin; it was so firmly attached to the femoral vein that an inch of the vessel was removed with it. This gland was two inches wide, and was so hard that it had to be divided with a saw. The patient died two months and a half later, and Mr. Power obtained a series of specimens showing the secondary growth in the lungs, ribs, and clavicles, and a large deposit in the ilium. The growths were all of the nature of round-celled sarcoma embedded in a vascular matrix of true bone.

THE ANTIDYSPNOEIC ACTION OF IODIDE OF POTASSIUM has been studied by PROFESSOR SÉE, who concludes that this drug antagonizes dyspnoea in a double manner: 1. By liquefying the products of catarrhal secretion that block the bronchi and hinder the entrance of air; and by facilitating gaseous changes between the intrapulmonary and the ambient air. At the same time it acts on the respiratory centre and on the pulmonary circulation. 2. By causing a true pulmonary hyperæmia, which has the effect of accelerating the circulation and of increasing the changes. Venous stases disappear under its influence, asphyxia diminishes, and respiration becomes freer and easier. Iodine is not only a respiratory, but a pulmonary medicament. Whether the hyperæmiatic action of the iodine is due to excitation of the vaso-motor centre, and especially of the vaso-dilator nerves or not, it matters little. Calmeil has shown that iodine accumulates in enormous quantities in the lungs, as well as in other organs, and facilitates the pulmonary circulation.

THE FORTIETH ANNUAL MEETING.—We desire to call special attention to the fact that the time for the annual meeting of the Association is not far distant. All members and others that contemplate contributing papers to the Sections should communicate with the officers of the Section, in which their papers will be read, as soon as possible. We learn that excellent programmes

are already arranged for several of the Sections. In preparing papers for the Sections the rules of the Association, in regard to papers, should be borne in mind. These rules are printed in the department of Association News, where may be found also a list of the officers of Sections and their addresses.

ASSOCIATION NEWS.

American Medical Association. Fortieth Annual Meeting.

To be held at Newport, R. I., June 25, 26, 27 and 28, 1889.

Special Attention is called to the following Rules of the Association:

It shall be the duty of every member of the Association who proposes to present a paper or report to any one of the Sections, to forward either the paper, or a *title* indicative of its contents, and its *length*, to the Chairman of the Committee of Arrangements at least one month before the annual meeting at which the paper or report is to be read. It shall also be the duty of the Chairman and Secretary of each Section to communicate the same information to the Chairman of the Committee of Arrangements concerning such papers and reports as may come into their possession or knowledge for their respective Sections, the same length of time before the annual meeting. And the Committee of Arrangements shall determine the order of reading or presentation of all such papers, and announce the same in the form of a programme for the use of all members attending the annual meeting. Such programme shall also contain the rules specified in the By-laws and Ordinances concerning the consideration and disposal of all papers in the Sections.

No report or other paper shall be entitled to publication in the volume for the year in which it shall be presented to the Association, unless it be placed in the hands of the Committee of Publication on or before the first day of July. It must also be so prepared as to require no material alteration or addition at the hands of its author.

Every paper or address received by this Association, or by a Section, and ordered to be published, and all reports of Committees, and all plates or other means of illustration, shall be considered the exclusive property of the Association, and shall be published and sold for the exclusive benefit of the Association.

ORDINANCES.

Resolved, That the several Sections of this Association be requested, in the future, to refer no

papers or reports to the Committee of Publication, except such as can be fairly classed under one of the three following heads, namely: 1. Such as may contain and establish *positively* new facts, modes of practice, or principles of real value. 2. Such as may contain the results of well-devised original experimental researches. 3. Such as present so complete a review of the facts on any particular subject as to enable the writer to deduce therefrom legitimate conclusions of importance.

Resolved, That the several Sections be requested, in the future, to refer all such papers as may be presented to them for examination by this Association, that contain matter of more or less value, and yet cannot be fairly ranked under either of the heads mentioned in the foregoing resolution, back to their authors with the recommendation that they be published in such regular medical periodicals as said authors may select, with the privilege of placing at the head of such papers, "Read to the Section of the American Medical Association on the day of 18 . ." (Vide *Transactions*, vol. xvi, p. 40.)

Resolved, That no report or other paper shall be presented to this Association unless it be so prepared that it can be put at once into the hands of the Permanent Secretary, to be transmitted to the Committee of Publication. (Vide *Transactions*, vol xvii, p. 27.)

NOTICE TO EXHIBITORS.

Intending exhibitors should address Dr. Chas. A. Brackett, Chairman Sub-Committee upon Exhibits.

The following classes of applications will be entertained:

1. Medical books and stationery, charts and diagrams, busts, portraits, engravings, photographs, etc.
2. Hospital and ambulance plans and models.
3. Surgical instruments and supplies, general and special (gynæcic, obstetric, orthopedic, laryngeal, otic, ophthalmic, dental, etc.).
4. Microscopes, analysis outfits, and electro-galvanic apparatus.
5. Pharmaceutic products.
6. Rubber goods applicable to medicine and surgery.
7. Invalid furniture.
8. Invalid foods.
9. Sanitary appliances, as ventilators, filters, w. c. basins, traps, and similar necessities, and disinfectants.

As a large attendance is probable, while the space available for exhibits is comparatively limited, the advantage of early application will be perceived.

Choice of space will be given in accordance with the date of application.

Applicants should state the character of their proposed exhibits, that they may be assigned to their respective groups:

The Sub-Committee reserve the right of rejection, in case of apparent reason.

HORATIO R. STORER, M.D.,

Chairman Committee of Arrangements.

OFFICERS OF SECTIONS.

The first name given under each Section is that of the Chairman, the second that of the Secretary.

Practical Medicine: F. C. Shattuck, M.D., 135 Marlborough St., Boston; G. A. Fackler, M.D., 504¹/₂ Elm St., Cincinnati.

Surgery and Anatomy: N. P. Dandridge, M.D., Cor. 4th and Sycamore Sts., Cincinnati; W. O. Roberts, M.D., 1541 Second St., Louisville, Ky.

Obstetrics and Diseases of Women: W. H. Wathen, M.D., Louisville; A. B. Carpenter, M.D., 143 Euclid Ave., Cleveland.

State Medicine: J. Berrien Lindsley, M.D., Nashville, Tenn; S. T. Armstrong, M.D., U. S. Marine-Hospital Service, New York.

Ophthalmology: George E. Frothingham, M.D., Ann Arbor, Mich; G. C. Savage, M.D., Nashville, Tenn.

Laryngology and Otology: W. H. Daly, M.D., 71 6th Ave., Pittsburgh, Pa.; E. Fletcher Ingals, M.D., 70 State St., Chicago.

Diseases of Children: J. A. Larrabee, M.D., 1823 Baxter St., Louisville; Chas. G. Jennings, M.D., 544 Jefferson Ave, Detroit.

Medical Jurisprudence: Jas. G. Kiernan, M.D., Central Music Hall, Chicago; T. C. Evans, M.D., Cor. Ann and Aliceanna Sts., Baltimore.

Dermatology and Syphilography: L. Duncan Bulkley, M.D., 4 E. 37th St., New York; Wm. T. Corlett, M.D., Cleveland, Ohio.

Oral and Dental Surgery: F. N. Rehwinkel, M.D., Chillicothe, Ohio; E. S. Talbot, M.D., 125 State St., Chicago.

SECTION ON DISEASES OF CHILDREN.

Preliminary Programme for the Meeting of 1889.

The following named gentlemen have promised papers on the following subjects:

C. R. Earley, M.D., Ridgway, Pa., "Scarlatina."

John A. Robison, M.D., Chicago, Ill., "Treatment of Heart Diseases in Children."

J. C. Wilson, M.D., Philadelphia, Pa., "Abdominal Neuralgias of Children."

E. M. Brush, M.D., Mt. Vernon, N. Y., "Cows' Milk for Infants' Food."

David S. Booth, M.D., Sparta, Ill., "Epilepsy a Disease of Childhood."

The following have promised papers, but have not yet announced the subjects:

Edmund C. Wendt, M.D., New York, N. Y.

John A. Jeffries, M.D., Boston, Mass.

J. M. Keating, M.D., Philadelphia, Pa.

Wm. H. Edwards, M.D., Philadelphia, Pa.

Jerome Walker, M.D., Brooklyn, N. Y.

H. E. Pelle, M.D., Louisville, Ky.

W. B. Atkinson, M.D., Philadelphia, Pa.

Others that wish to read papers before this Section are requested to communicate with its officers.

SECTION ON STATE MEDICINE.

In addition to the list of papers published in *THE JOURNAL* of March 2, the following Committees will report, and papers be presented to the Section on State Medicine.

Report of the Committee on Uniform Medical Legislation in the United States. Dr. Perry H. Millard, Chairman. [At the last meeting this Committee was given another year to report.]

Report of the Committee on Fœticide. Dr. I. N. Quimby, Chairman. [This Committee was directed to report to the Section on State Medicine by resolution of the Association.]

"Medical Legislation in the United States," Dr. Perry H. Millard, St. Paul, Minn.

"Is it Detrimental to the Health of Passengers on Ship-board to Convey to Port the Bodies of Persons who Die at Sea of Non-contagious Diseases?" Dr. I. N. Quimby, Jersey City, N. J.

"Personal Disinfection in Scarlatina," Dr. L. D. Waterman, Indianapolis, Ind.

"The Climatic Causation of Consumption," Dr. H. B. Baker, Lansing, Mich.

"The Importance and Essential Needs of Local Boards of Health," Dr. W. C. Rives, New York, N. Y.

Announcement will be made in *THE JOURNAL* of the titles of the proposed papers as soon as the Secretary is notified.

SECTION OF LARYNGOLOGY AND OTOTOLOGY.

The Officers of this Section, which was created at the last meeting, have already received several promises from prominent specialists throughout the country, to read papers at the coming meeting. Several others have given partial promises, many of which, we believe, will soon be made absolute, and we feel assured already of a successful meeting.

We urge all laryngologists and otologists in the country, who have a local or National reputation, and who are in good standing with the regular profession about them to do something for the benefit of the profession through this Section. All are *specially requested* to send their names and addresses to the Secretary, whether they are likely to attend the meeting or not.

E. FLETCHER INGALLS, M.D., Sec'y,

70 State St., Chicago.

W. H. DALY, M.D., Pres't.

SECTION ON OBSTETRICS AND GYNECOLOGY.

We are pleased to learn from Dr. Wathen, of

Louisville, Chairman of the Section on Obstetrics and Gynecology, that he has the promise of forty papers for the Newport meeting, in June. The meeting of this Section will probably be one of the most interesting in the history of the Association, for nearly all of those who will read papers have done work of scientific excellence in obstetrics or gynecology. A programme of the Section will be published at an early date.

SOCIETY PROCEEDINGS.

Gynecological Society of Boston.

Regular Meeting, November 8, 1888.

THE PRESIDENT, HORACE C. WHITE, M.D.,
IN THE CHAIR.

Alvah B. Dearborn, M.D., of Somerville, Mass., was elected to active membership.

DR. W. S. BROWNE showed a

NEW DEVICE FOR USING ADHESIVE PLASTER.

The strip of plaster is cut in two and the ends are reunited by a strip of thin rubber gummed to the back side of the plaster. The pull of the rubber, after application, keeps the edges of the wound in apposition.

DR. WHITE referred to the use of a strip of silk tulle secured in place by collodion as an excellent dressing for wounds.

PATHOLOGICAL SPECIMENS.

DR. F. L. BURT showed a pair of *ovaries and tubes* that had been removed the day before. The patient, who was about 50 years of age, had suffered for the last twenty-five years, and more especially during the last six years. A laparotomy was performed, making an incision rather longer than usual. Pus-tubes at once presented at the opening, each the size of the double fist. They were very firmly adherent and were removed with difficulty, together with the ovaries. The patient was comfortable when the case was reported.

DR. G. W. JONES exhibited some *membranous strips* that came from a patient that had a history of an abortion last February, and an operation for lacerated cervix last May. Two weeks ago he confirmed her supposition that she was about two months pregnant. A day or two later, she brought him a membranous sac which she said came away from the vagina. The sac, which was filled with jelly and contained certain granules, had burst. Last Monday he found a similar membranous sac presenting at the os uteri, which he removed. Both specimens were somewhat pear-shaped, the size of a silver dollar, and were corrugated. He had not decided upon their character. There had been no pain or hæmorrhage.

DR. C. W. STEVENS said that he had once removed from a young unmarried woman, who believed herself to be pregnant, a very large collection of little cysts, which was probably a mole or a cystic degeneration of the placenta. Previous to the removal of the mass there had been considerable hæmorrhage. He would suggest that Dr. Jones' specimens might be of this character.

DR. H. O. MARCY exhibited *two sets of ovaries and tubes* that he had removed about four weeks previously. The histories of the two patients were so similar that each might represent the other. Both patients were in middle age. One had been an invalid for twelve years, of which time the last six years had been passed in bed. The other patient had been an invalid for seven years, most of which time she had been in bed. Both had great pelvic discomfort for the whole period of four weeks, and to such an extent that both had become morphine *habitues*. The operations were performed in the ordinary manner with an incision in the median line about 2 inches long. Through this, opening the ovaries were brought out one at a time, and the broad ligaments, while on stretch, were stitched across with a tendon by the shoemaker's stitch, which included the Fallopian tube close to the fundus uteri. The ovary and tube were then cut away, the peritoneal edges of the stump were sewed together with tendon, and the stump was dropped back into the pelvis. While these operations were being performed, a stream of nascent oxygen gas was directed downwards by means of a tube, the outlet of which was about a foot above the abdominal incision. Thus used nascent oxygen is claimed by some to be antiseptic. There is no foundation for this claim, but it is aseptic and, moreover, it is very invigorating to the operator and his assistants, and, in case of difficulty with the breathing of the patient, its easy accessibility might be very beneficial in restoring her respiration. These ovaries are all enlarged and they were still functioning when removed. The tubes are large and convoluted, and some of the processes of the fimbriated extremity are much thickened.

DR. MARCY also showed a *very large fibroid* that he had removed *per vaginam* from a patient, æt. 41, who had been healthy till two years ago, since when she had been constantly flowing to a greater or less extent. The os uteri was dilated to about 1½ inch and the whole pelvis was filled. The question arose, could the tumor be removed *per vaginam*? The attempt was made and it was removed in nine or ten pieces. The spoon-saw was first used and then the portion thus separated was cut away with curved scissors. This was repeated till the whole tumor had been removed. The cavity of the thin-walled uterus was then packed with iodoform wool. The patient made a good and rapid convalescence, and the uterus measured only 3 inches when she left the hospital.

The tumor weighed about 3 lbs. Dr. Marcy said that two years previously he had removed in pieces a tumor which weighed 4 lbs., and that this is the largest on record as removed *per vaginam*.

DR. E. C. KELLER asked if the hæmorrhage continued at the menses?

DR. MARCY replied that the menstrual flow had been normal.

DR. KELLER said some time ago she had removed a tumor that weighed 14 ozs. The patient did well, but at the menses there was profuse flooding, which resisted everything till the ext. *hydrastis canadensis fl.* was used, and this acted like a charm. The dose was 20 drops three times a day. The uterus had decreased much in size and there was nothing in the cavity of the uterus.

The Society then discussed

SOME POINTS IN THE APPLICATION OF ELECTRICITY AS A MEANS OF TREATMENT OF FIBROIDS OF THE UTERUS.

DR. F. L. BURT referred to the pathological specimens exhibited by himself and remarked that they showed how useless it would have been to expect any good result from the use of electricity in this case, although it seemed to be a suitable case for its employment. As a matter of fact it had been tried, with the result of causing more pain and affording no relief. If administered in too strong current or for too long a time, it might produce sepsis and death. This was a case in which puncture would have been dangerous. Without doubt, electricity in suitable cases works well.

DR. C. W. STEVENS spoke of Apostoli's abdominal electrode of clay as a nuisance, according to his experience after faithful trials. It is filthy and wet, and it is difficult to keep it at the right temperature. In its stead he has had made and now uses an electrode (now exhibited) made of flexible sheet brass, rectangular in shape and about 7×9 inches in size. This is covered on its under side by a pad of several thicknesses of antiseptic gauze, cut in the same shape as the electrode and somewhat larger than it in size, so that, when the edges of the gauze are folded up over the ends of the brass plate, they can be held firmly in place by rubber bands slipped over the ends of the plate. This plate can be easily bent into suitable shape to fit the abdomen of any patient. It is simple and clean and, if desirable, the physician can have different ones for each patient. In using, the antiseptic gauze is wet sufficiently with hot water. The other pole he sometimes uses intrauterine and sometimes intravaginal. He has noticed the external measurements diminish 2 inches.

DR. A. P. CLARK said that McIntosh's diaphragm is a very ingenious instrument and it works well. He asked if Dr. Burt referred to galvanism in his remarks. If he had not meant

galvanism Dr. Clark might take exceptions, for he has found faradism to be very beneficial.

DR. BURT said that he has been using an abdominal electrode that he likes very well, and he believes it to be better than the one shown by Dr. Stevens. Cloth, of any desired size and number of thicknesses, is wet with warm water and laid on the abdomen. On top of this is placed a plate of block tin, which is heavy enough to stay in place and is a good conductor.

DR. H. O. MARCY asked, what is the effect on the skin of electricity passing through wet cotton?

DR. STEVENS replied: There is produced a temporary erythema or redness by congestion of the capillaries.

DR. MARCY: What strength of current is used?

DR. STEVENS replied that he used no galvanometer and that he has been guided by the feelings of the patient.

DR. BURT replied that a current of 100 milliamperes, which is the strongest he has used, produced a deep reddening of the skin with a sensation resembling that given by a mustard plaster, and this description of it is very frequently used by the patients. In a very few patients an eruption is produced, though he cannot tell why it is so. This is very similar to the eruption of chickenpox. There are vesicles filled with fluid which is later changed to pus.

DR. STEVENS said that he had once seen an eruption similar to that described by Dr. Burt, and he had thought it due to the strength of the current.

DR. MARCY: Is the skin cool or hot to the hand after having used the cotton electrode?

DR. BURT: It is warm at first, but it cools rapidly.

DR. MARCY said that he has used Martin's electrode, which contains a considerable amount of cold water through which the current passes, and yet the patient at once complains of warmth. He feels sure that the thin cotton pad could not be used when such high currents are employed as he is accustomed to use.

DR. BURT remarked that he generally employs a current of from 60 to 70 milliamperes. The patient never complains after it has been used and not especially at the time. He uses hot water for wetting his pad.

DR. MARCY said that Apostoli emphasized that the electrode must be sufficiently cold to cause the patient to shrink, when it is first applied, and that high currents must be used. Dr. Marcy himself has used as high as 350 milliamperes in few cases of large growths. Apostoli says that we should intensify the current, and he sometimes employs stronger currents than Dr. Marcy has used. Dr. Marcy said that both Apostoli's and Martin's electrode fits all of the irregularities of the abdomen. Martin's electrode consists of a hollowed metallic disk, across the bottom of

which parchment is stretched. The disk is perforated to allow filling with cold water, and the opening can then be stopped with a cork. About a pint and a half of water is used.

DR. BURT said that cold is not necessary when a light current is used and that heat is more agreeable than cold.

DR. WHITE: How long should a current of 100 milliamperes be used?

DR. BURT: From six to eight minutes.

DR. WHITE: How long should the high currents be employed?

DR. MARCY: From five to eight minutes with 350 milliamperes.

DR. WHITE: How often should they be employed?

DR. MARCY said in reply, that in a few cases he has employed it daily until five or six applications had been made. The positive pole in the uterus will necrose tissue, and hence there is pain and soreness. According to Apostoli sepsis should be emphasized; for the septic ferments may easily grow in such partially necrosed tissue, which forms a good nutrient material for them. About two and a half years ago there were reported here in Boston 12 cases with 2 deaths. These may have been caused by sepsis. Apostoli says that the vagina should be thoroughly clean.

DR. WHITE asked if any accidents had been caused by Apostoli's method. To this no one replied. He then asked if any good had resulted from Apostoli's method.

DR. W. S. BROWN offered the criticism that this was too narrow a question, since Dr. Cutter had used electricity for fibroids many years ago.

DR. MARCY said that Dr. Cutter used to employ great currents and that he used no measurements. Once Dr. Garratt had interpolated a galvanometer, which showed that the current was passing through from pole to pole, and thus answered the criticism that it passed around. At this time it was believed that electricity was too dangerous to be used. But the great secret of Apostoli's success is the use of one pole in the uterus and the large abdominal pad. In reply to the question, whether any good had resulted, he would say that at first he was a doubter, but after further conversation with Apostoli, when he came to Boston, he began to follow him. Dr. Marcy has now made several hundred applications to about twenty patients. Each patient thinks herself better, and he himself is sure that some are better. In one case, in particular, the woman could not walk across the street nor ride in a horse-car before the applications. The growth filled the pelvis and pressed on the pelvic organs. She received from twelve to fifteen applications of a current of 250 to 350 milliamperes two to three times a week. Some months later the growth had diminished two-thirds or three-fourths, and the woman is now at work at her household duties.

DR. WHITE: How soon after the application should the patient be permitted to leave the office?

DR. MARCY replied that he never uses electricity for this purpose in the office. Dr. Smith, of Montreal, does so use it in some cases with apparent safety.

DR. BURT replied that he causes the woman to lie down for about half an hour after receiving an application of 50 to 75 milliampères. He had recently a patient who had nearly flowed to death, and there was necessity for either electricity or removal of the ovaries. He gave the positive current on the uterus with an aluminum wire electrode, which is claimed to be safe, but it does corrode, and when the eschar comes away there may be hæmorrhage.

Stated Meeting, December 13, 1888.

THE PRESIDENT, HORACE C. WHITE, M.D.,
IN THE CHAIR.

DR. W. SYMINGTON BROWN read a paper entitled

CHRONIC CYSTITIS IN WOMEN

in which he said: The bladder is almost as movable as the uterus. We are told in books that its transverse is greater than its vertical diameter; but I suspect that the proportions must be reversed when it holds a gallon of urine, as it sometimes does. Then, again, we are told and told truly, that highly concentrated urine irritates the bladder, and that the irritation may even end in cystitis. But it is not so generally known that "hysterical urine," of low specific gravity, almost destitute of saline ingredients, is also a common cause of irritation and pain.

Acute cystitis is a very rare affection in women; some authors say that it never occurs, except as a sequence of traumatic injuries. At one time many physicians believed that cystitis resulted from using forceps in labor; and I have no doubt that this erroneous belief acted as a bugbear to curtail the employment of that useful instrument. In our day, very few competent practitioners refrain from using forceps on this account. The probability is that cystitis more frequently results from long-protracted labors which should have been shortened by applying forceps or by turning. I have seen only one case of acute cystitis in a woman (apparently caused by swallowing tincture of cantharides with the view to produce abortion), and that case may have been due to other suspected agencies. I have also seen three cases in men, during our civil war, resulting from gunshot wounds in that region. Unfortunately, chronic cystitis is far from being a rare affection in woman. Many of the cases occur after tedious labors; a few are caused by errors in diet, such as highly spiced food, fermented liquors,

etc.; but in my opinion, the larger number result from not emptying the bladder often enough. A false modesty and a genuine lack of opportunity combine to bring about this disastrous effect. It is a curious fact in the history of modern civilization that, with all our pretensions to gallantry, so little has been done in large cities to accommodate women in this respect. Some one has asserted that the amount of soap used in a nation is a fair test of the advance it has made in civilization. I would suggest, as an additional gauge, the number of public urinals for women and men.

When cystitis has lasted for years, the mucous membrane of the bladder may be detached in shreds, and the inflammation spread to the muscular and even to the serous coats. In most cases of long standing the bladder is contracted to one-half, or even less, of its normal capacity. The mouths of one or both ureters become thickened and congested, sometimes occluded, and the urine undergoes changes incidental to decomposition. Small quantities of blood, pus, and mucus frequently appear in it; and, instead of the normal acidity, it is voided in an alkaline condition. Under these circumstances, it is possible, and even probable, that the inflammation may progress upwards, affecting the ureters, and, finally, one or both kidneys. And it often happens that the cystitis excites a reflex pain in neighboring organs, sometimes in parts at a considerable distance from the original seat of inflammation. The treatment essentially consists in affording the bladder as much rest as possible, and in other ways allaying the inflammation. But to give rest to an organ constantly in use, night and day, must prove a somewhat difficult task. I have quite recently had a case, which occurred in a married man with a severe gonorrhœa, who was seized with typhoid fever, and after the usual watery stools for two days the urethritis abated. I attribute the reflex cure to the diarrhœa. Idiosyncrasies seem to affect the bladder even more than other organs; and in women more than in men, age must be taken into account. Before puberty, during the child-bearing period, and after the menopause, constitute eras during which bladder affections essentially differ. The following interesting (personal) case belongs to the last mentioned period. I first visited Mrs. B. on Christmas-day, 1887. She is a married lady with a grown-up family, about 63 years of age, who had always enjoyed health until 1884, when she began to suffer pain in the bladder, accompanied with frequent calls to urinate, night and day. During the whole three years she has never been able to retain her urine for more than an hour at a time, and sometimes she was obliged to use the vessel every half hour or so. Mrs. B. had been under the care of several physicians, regular and irregular. Although naturally of a placid, happy dis-

position, her face showed marks of suffering and anxiety. Pulse 85; temperature 99.5°. Her urine, drawn with a soft catheter, contained pus, mucus, and crystals of the triple phosphates. There was no uterine or ovarian disease. A small caruncle, growing at the lower edge of the meatus urinarius, was removed by means of a wire snare. A similar but smaller growth was found at the neck of the bladder, and this was also removed. For a period of six weeks, she took a tablespoonful of the following solution every four hours during the day; and also used it as an injection into the bladder every night and morning:

- | | |
|---------------------------------|--------|
| R. Benzoic acid, pure | ℥ij. |
| Biborate of soda | ℥iv. |
| Distilled water | ℥vj. ℥ |

She took lithia water as a drink for several weeks, with apparent benefit. All kinds of fermented liquor were absolutely forbidden. Her diet was carefully regulated. Salt meat, salt fish, pork, lobster, beans, highly spiced soups, fried food, and pastry were prohibited. The usual directions to overcome constipation were given. Attention was paid to position in bed, by raising the pelvis with graded cushions, so as to avoid contact of the urine with the *trigonum vesicæ*, the most sensitive spot in the bladder. At the end of six weeks the urine was free from pus and triple phosphates, and it could be retained about two hours. Early in May, 1888, she considered herself cured. As the bladder had become much contracted, I made an attempt, towards the close of the treatment, to dilate it by means of tepid salt water from a fountain syringe. Dilatation should be effected very gradually; for there is some risk of paralysis from overdistention; and it seems possible, when the ureters are abnormally dilated, that the kidneys themselves may be injured. Reference was then made to the efficacy of hygienic, comfortable surroundings, admirable nursing and a contented coöperation on the part of the patient.

DR. HENRY M. FIELD was especially struck with the allusion to the relief or cure of gonorrhœa by the revulsive action of a sharp hydragogue cathartic influence brought to bear upon the bowels; because this practical point in therapeutics was seldom illustrated. Some years ago a quack in Paris coined golden opinions and guineas by the use of an anti-gonorrhœal, which, upon analysis by Fabre, was found to consist of a tincture of colocynth. Fabre's method consisted in giving the patient half a tablespoonful of the tincture (one ounce colocynth pulp macerated in one pint hock or sherry) before breakfast every morning; this omitted every fourth day, and the treatment continued until twenty-seven to thirty doses had been taken. Dr. Field had had success with this remedy, when the balsamic treatment alone had failed. The patient

is thereby cleaned out, not alone as to the alimentary canal, but in blood-vessels; and the bitter of the tincture served as tonic and eupeptic. The application for similar principle in chronic systitis is obvious. He was surprised that Dr. Brown had not made allusion to the use of balsamic remedies. Dr. Field, for years, had made large account of turpentine and sandalwood oil. The very necessity of their elimination—their resinous matter being carried out of the system through the kidneys—assumed a local action of a partly counter-irritant and alterative character upon the cystic mucous membrane. They were not adapted to acute cystitis, but were very effective in the chronic variety of the disease. Quinia acts in much the same way. Dr. Field's first discovery of its virtue was an accident. He gave it to a patient who was nearly cured of inflammation of the bladder, but had reached the stage when he seemed to be standing still, simply as a tonic. The quinia took hold upon the bladder at once, and apparently completed the cure.

DR. A. P. CLARKE said that, in the main aspects, he coincided with the reader, especially in his remark that he had rarely seen cases of acute cystitis following childbirth. Retention of urine does often occur after laceration of the cervix and other injuries. Cystitis also follows caruncle, fissure of the urethra, and gonorrhœa. Cases of idiopathic cystitis are not as common as has heretofore been believed. Cystitis often results from falls, blows, flexure of the uterus, great distention of the bladder, and unskillful employment of the catheter. The extension of inflammation from vulvitis and vaginitis is an occasional cause of vesical disturbance. So also is the increased vascularity in the parturient women liable to produce over-distention and vesical inflammation. He regarded the mucous coat of the bladder as most sensitive to inflammation; thence the inflammation is liable to extend to the other coats and adjacent structures. Sometimes the disease extends to the uterus, the kidneys, and peritoneum. Under such circumstances treatment will often prove quite unsatisfactory. He is accustomed to use the hot-pack, hot douches, and baths. Electricity (in the form of Faradism), with one pole near the urethra and the other over the bladder, gives relief after the lesions have been attended to. Saline laxatives and mineral waters sometimes help. Bland diluents are of the greatest benefit, especially where the urine is loaded with abnormal products. Opiates are to be avoided as much as possible, and, when used, their local employment is to be preferred. Benzoic acid, in combination with borax, mentioned by the reader, is an old remedy, but it has been a favorite one with the speaker since its endorsement by Dr. Emmet several years ago. Washing out the bladder is often of much benefit; but extra care should be exercised lest the mucous

and muscular coats (which have frequently undergone degeneration) be overstrained, and permanent injury follow. In cases of protracted inflammation, washing out the bladder with a solution of nitrate of silver, (30 grains to the ounce) often yields excellent results. Attention should also be given to the diet. Butcher's meat should generally be avoided, as it is liable to increase the urates and other morbid products which irritate the urinary passages. Dr. Clarke had seen a few cases following delivery; but there was generally a previous history of catarrh in the bladder or gonorrhœa. In one case a large calculus was found in the bladder. Dr. Emmet's operation for an artificial vesico-vaginal fistula is a valuable expedient in severe cases. Dr. Clarke also mentioned a case in his own practice which was permanently relieved by rapid dilatation of the urethra. Since then he has continued to resort to that method in cases where tenesmus is a marked feature, and where the parts around the meatus are contracted and hypertrophied.

DR. ORIS E. HUNT asked if an attack of cystitis occurring a week after delivery in a forceps case would not be called acute traumatic cystitis? [Answer by Dr. Brown: Yes; but I have not seen one.] Dr. Hunt said that he has seen it several times. Little benefit can be obtained except: *a.* From position, which should be horizontal, with the pelvis a little elevated. *b.* From the hot pack (especially in an attack of acute cystitis). A napkin, folded in several thicknesses and of sufficient size, is wrung out of hot water and placed on the abdomen over the bladder. This should be covered with rubber tissue, and this in turn with several thicknesses of flannel, covering a considerably larger extent than the wet napkin itself, and the whole held in place with a bandage. It should be changed twice a day. *c.* From continual drainage. For this purpose the hard rubber catheter has failed; but a soft rubber male catheter of large size, introduced with the aid of cocaine, and retained by plasters around the body, serves an excellent purpose. This may be retained for weeks, the end of the catheter being put into a bottle, which may be kept in the bed to catch the urine. *d.* From internal irrigation through the kidneys. Large quantities of water must be drunk. The patients will not take Cochituate or other common water, but they will drink two or three quarts of Poland water. This not only dilutes the urine, but it actually washes out the urinary tract. *e.* Also from external irrigation, which is done by attaching to a fountain syringe a catheter with a forked tube, provided with a stopcock. The bladder is first filled; but should not be too much distended, and then it is allowed to run out and the bladder is again refilled. This is repeated for ten or fifteen minutes. For the irrigation fluid plain water is used, or a little borax may be added.

The temperature of the water is a very important point; before stating the degree that he considered best, the speaker asked Dr. Brown what temperature he preferred. [Answer by Dr. Brown: Blood heat, *i. e.*, about 100° F.] Dr. Hunt said that he also considered this to be the proper degree, and he has seen harm result from the use of water of too low temperature. He has not derived much benefit from internal medication. In the late stages he uses buchu, but does not believe that it does much good, except as a placebo.

DR. J. F. FRISBIE said that he had not had much experience in this class of cases. The last case he saw followed a very severe childbirth. In reply to his questions he was told that the woman had passed urine freely. On the third day there was much pain, and then he found out that there had been only dribbling. She had acute cystitis, which lasted fourteen days. He prescribed sulphate of magnesia, and she drank Apollinaris water freely. The wet pack was used, and there was a good recovery.

DR. L. F. WARNER said that this class of cases is one of the most difficult that he has been called upon to treat. He has seen a great many cases of acute cystitis, and he believed that most of the chronic cases were once acute. Occasionally cases are seen which have been caused by prolonged retention, *e. g.*, in the case of shop-girls. The urine decomposes in the bladder and it contains bacteria. He thought that Dr. Hunt's treatment was good, but that it alone would not cure very bad cases. In acute cases he always gives calomel, Dover's powder, and hyoscyamus. Fifty years ago dependence was largely placed on derivatives in the treatment of gonorrhœa. Epsom salts were always used, and the patients learned to expect them. In chronic cystitis he had obtained the best success from the use of irrigatives, and he prefers a solution of corrosive sublimate, followed by iodoform. He uses a double canula with a stopcock, and a fountain syringe. He first washes out the bladder thoroughly with water at 100° F. The bladder is gradually filled with water till the patient begins to complain, then the stopcock is opened, and an outflow is made, while at the same time the corrosive sublimate solution is allowed to run in. It is quite important to keep the bladder distended, so that the fluid may come in contact with all portions of the mucous membrane. The irrigation is continued for some time, and is followed by an injection of iodoform, which is left in the bladder. The urine should be kept as nearly neutral as possible. In reply to the question as to the strength of the solution of corrosive sublimate that he would recommend, Dr. Warner said that the sensibility of patients varies: one will bear 1 to 5,000, while others will not bear 1 to 10,000. He begins with a weak solution and feels his way along. Sometimes a douche into the bladder of a solution of

quinine (*e.g.*, a drachm to a pint of water) will give much relief. A solution of the sugar of lead was used in one case. He emphasized the importance of getting the system into as good a condition as possible to secrete healthy urine.

DR. FRISBIE asked if it is especially advantageous to have the water boiled before using?

DR. WARNER: I don't know about that. It is always easier to bear than cold water.

DR. HUNT asked if frequent micturition is not often relieved by drainage by means of a retained catheter?

DR. WARNER replied that that is true if the patient can bear it. The effect of cocaine, which has been suggested, is not lasting.

DR. W. S. BROWN emphasized that the continued use of cocaine is dangerous on account of its constitutional effects.

DR. F. L. BURT said that this is a most important class of cases, and one most difficult of treatment. Some cases can only be cured by making an incision into the bladder through the vagina, *i. e.*, by making an artificial fistula, and thus securing drainage. Irrigation is an important factor in the treatment. In one case, a douche of corrosive sublimate (1 to 2,000) cured a cystitis of twenty years' duration. Some cases, however, are not apparently affected at all by the irrigation. He has lately seen a case in which a 1 to 500 solution had no effect. He believes that one important cause of cystitis is the continual flowing over the meatus of a 1 to 2,000 solution of corrosive sublimate for an operation. To avoid this, after commencing with the sublimate solution, he concludes the operation by substituting hydro-naphthol.

DR. J. H. WOODS said that he saw a case two years ago that was cured by the use of Poland water. The young man had had an attack of gonorrhœa, and he was passing very acid urine. Alkalies were administered without any effect. After a time he passed into the hands of a homœopath, who flushed him with Poland water and cured him.

DR. A. L. NORRIS had seen a few cases following difficult labor. He had been accustomed to treat them with irrigation, for which he employed a double silver catheter. These douches were given twice a day for several days, with excellent results. Hot fomentations are of benefit, as also are alkalies and anodynes given internally.

DR. HUNT asked if the catheter had been used in these cases before the cystitis had appeared?

DR. NORRIS replied that it had; but that he was accustomed to use a new catheter for each patient.

DR. HUNT said that he had a suspicion that many attacks of acute cystitis were caused by the introduction into the bladder of foul discharges from a catheter that had not been thoroughly cleansed after using.

DR. BURT said that the catheter was a very important factor in the causation of cystitis. Many old men use their catheter several times a day, lay it upon their bureau, and have no bad results; but women cannot do so. Not only must their catheter be carefully cleansed, but the external parts must be washed.

DR. NORRIS had never thought it necessary to wash the parts before using the catheter in a parturient case; but he thought the point worthy of consideration.

DR. BURT thought it a good plan to wipe the meatus with cotton wet with some antiseptic solution, and then press it down so as to separate the vulva, and leave it there.

DR. HELEN L. BETTS referred to attacks of vesical irritation due to pressure of the clothing, which were relieved by the removal of pressure and weight.

DR. HUNT wished to emphasize the point noticed by the reader of emptying the bladder as often as the desire occurred.

DR. S. N. NELSON said that the urine in cystitis contains a greater or less amount of pus in the sediment, and there is present a small amount of albumen proportionate to the pus. Bacteria termo are found in great numbers. The most important factor in the causation of cystitis, whether in man or woman, is the introduction into the bladder of bacteria, and, as a consequence, a fermentation of the contents of the bladder is set up. In this way may be explained most of the cases which have been referred to as occurring during an attack of gonorrhœa, or after labor. The means by which the germs are most commonly introduced is the catheter, which has not been properly cleansed. To avoid this, it is a good plan to soak the soft rubber catheter in a solution of corrosive sublimate (1 to 2,000) before its introduction; and, in the case of a patient who requires its use constantly, it may be left in soak when not in use. The meatus and vulva of the woman should be carefully cleansed with sublimate solution before the introduction of the catheter, and it is always a good plan to bring to aid the sense of sight when passing the catheter. If, unfortunately, in spite of all these precautions, an attack of cystitis is induced, or if a case is seen where the chronic stage has been reached, Dr. Nelson believes that more good can be done by local than by systemic treatment. In acute cystitis the drinking of large quantities of water so as to flush the uriniferous tract is an excellent procedure. It matters little in what form the water be taken, so long as the quantity is large. The imbibition of mucilaginous substances is desirable; and for this purpose flax-seed and slippery-elm teas are to be recommended. As an adjuvant, the neutralization of the urine until litmus paper no longer turns red is a great comfort to the patient; for, in acute cystitis, the urine has

become unduly acid, having undergone the acid fermentation in the bladder. This is easily effected by administering citrate of potassium. Local treatment, however, is the most effectual, both in acute and in chronic cystitis; and for this purpose irrigation by means of a double-tube catheter of soft rubber is best. The irrigation fluid should be a solution of corrosive sublimate as strong as can be borne. This will vary from 1 to 10,000 to 1 to 2,000, according to the temperament of the patient and the condition of the mucous membrane of the bladder. The water should be boiled to kill the germs contained therein, and then cooled. In acute cystitis a solution of boric acid may be advantageously employed for half an hour to an hour, in order to thoroughly cleanse the inner surface of the bladder, and the irrigation may then be completed with the sublimate solution, which should run from 10 to 20 minutes. The irrigation fluid is most effectual when somewhat warmer than blood heat, say about 102° F. After washing, the injection of an emulsion of iodoform is a good thing. The irrigation may be employed as above, once or twice a day, in aggravated cases.

DR. W. S. BROWN, in closing the discussion, said that he had left out the surgical treatment in his paper. There are many cases in which it is necessary to open the bladder by making an artificial vesico-vaginal fistula. This is good practice in hospitals, but it cannot be carried out so well when the patient is at home. Dilatation of the bladder should be carefully and cautiously attempted, because in some cases the bladder wall is thin, the mucous and muscular coats have disappeared, leaving only the serous coat, and rupture may occur after even moderate pressure.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR REGULAR CORRESPONDENT.)

Radical Cure of Inguinal Hernia—Surgical Treatment of Uterine Retroversion—New Method of Shortening the Round Ligaments—New York County Medical Association.

At the first regular meeting of the Academy of Medicine at which the new President, Professor Loomis, occupied the chair, Dr. Charles McBurney, whose admirable operation has of late become so popular among the surgeons of this city, read a paper on *The Treatment of Inguinal Hernia with Reference to Radical Cure*. As an introduction to the exposition of his own operation, which he said had been the result of much thought and labor, he presented some of the considerations which had led him to attempt a procedure different in some respects from any that had preceded

it. In 1886 he met with some cases in which a return of the trouble after operations for the radical cure of hernia convinced him that one great essential to success in any such operation was the complete removal of the sac. The first predisposing cause of hernia he believed to be the pouching of the peritoneum at the internal ring, and therefore, in order to cure a hernia, it was necessary first to prevent laxity at this point, and then to support the peritoneum firmly at this point. He referred to various procedures designed to completely eradicate the sac, and gave a somewhat detailed description of Macewen's method. This operation, when practicable, he said, undoubtedly removed the sac; but it was often difficult or impossible to carry out. In selected cases, however, remarkable results had been obtained with it. Ball's method of twisting the sac he spoke of as a somewhat blind one, not free from serious objections; while some sacs also were altogether untwistable.

In his own operation Dr. McBurney splits the anterior wall of the inguinal canal all the way up to the internal ring. This procedure he supposed at first was original with himself, but he afterwards learned that it had been previously practiced by Riessel. This, he said, exposed the whole length of the sac, and when this had been done the neck of the latter could be disposed of either by ligature or by suture. In this way it was very easy to restore to the peritoneum the natural smoothness which he regarded as another of the great essentials to success in any operation for the radical cure of hernia. In all cases where it is applicable he much prefers the ligature to the suture. The only certain method of closing the entire canal except that portion of it occupied by the cord, he went on to say, he believed to be the open treatment of the wound, and even this was very difficult in some respects. It was requisite, for instance, that the whole wound should be packed extremely closely in order to secure granulation throughout its entire length. The objection had been raised against cicatricial tissue that it melts away and in time yields, and it had also been urged that cicatricial tissue does not prevent the frequent occurrence of ventral hernia after laparotomy; but he was firmly convinced that the cicatricial tissue here was sufficiently strong and permanent for all practical purposes, while the circumstances after the operation referred to were entirely different from those met with after laparotomy. Some operators had practiced the method of sewing up or narrowing the internal ring; but in reality, since the ring was naturally open quite wide, the stitches were of no avail in narrowing it.

He then proceeded to give the details of the operation employed by him for the past two years. Careful antiseptic precautions having been taken, a free incision is made, beginning a little outside the internal ring, and this is rapidly deepened

over the whole length of the canal. The canal, when reached, is split up to the outer edge of the internal ring, and the deeper layers of the sac having been dissected off, the cord is separated from the sac up to a point a little within the abdomen. The sac is freed from all adhesions and omental attachments, if there are any, and is then held high up from the internal ring, in order to prevent the return of any portion of intestine or omentum; when a ligature is applied at the very highest point. In congenital hernia, however, it is often necessary to suture, instead of ligating.

The wound is left entirely open, and from four to eight stitches are used to fix together the skin and the tissues which form the upper wall. As many more are employed for the lower wall; but as the wound is unnecessarily wide, some tendon sutures are usually passed deeply through the skin and superficial fascia. Iodoform is freely dusted about the wound, and then it is very thoroughly packed with iodoform gauze. The rectal end of the wound, however, is sewed up without a packing, and a drainage tube inserted at its lower extremity. Great care is used in making the external dressings, and in order to prevent contamination by urine rubber bandaging is employed in the case of adults and a plaster of Paris casing in children. Frequently, also, the urine is drawn with a catheter for several days succeeding the operation. At least five or six weeks are required for the healing, but Dr. McBurney believes that this comparatively long period in the prone position is time well spent in such cases. None of his patients are allowed to wear a truss or support of any kind after the operation, as he regards such appliances as positively injurious under the circumstances.

The advantages which he claims for the operation are as follows: 1. It is the only method in which the sac is completely obliterated. 2. The walls are very firmly united throughout their length. 3. The wound being open, septic complications are avoided. 4. The rapidity with which the operation can be performed renders it applicable in all varieties of cases. He said he had now employed this method in thirty-six cases. There was one fatal case, but this result was due to alcoholism. In three the wound became infected and the healing was slow; although there was no general sepsis in any of them. In one case orchitis was set up, and in one there was a relapse of the tumor; the cause of this relapse being without doubt, in his opinion, the fact that the sac was not ligated sufficiently high up. In conclusion, he said that within the past week he had either personally seen or heard from thirty-one of the cases, and that the result in all was thus far perfect. Of the remaining cases, two could not be found, and two were still under treatment. The various steps of the operation were very clearly shown by means of large colored drawings taken

from life, and at the end of the paper Dr. McBurney presented a considerable number of the cases operated on for examination.

The surgeons who took part in the discussion were all unanimous in according the highest praise to the operation. Dr. L. A. Stimson, the first speaker, thought Dr. McBurney was deserving of special thanks for his use of the cicatricial packing to the peritoneum, as he thus came squarely out against the ancient idea that cicatricial tissue was weak and untrustworthy. One of the chief advantages of the operation, and one which had not been particularly dwelt upon in the paper, he said, was the very great freedom from the risk of septic processes which characterized it. There was no necessity for drainage, and no drainage was employed except at the lower end of the wound in the scrotum; the wound above being left entirely open. As to the simplicity of the operation in the matter of ligating the neck of the sac, and restoring the peritoneum to its normal state, he had nothing but the warmest admiration to express for this also.

To realize the full advantages of the operation it was only necessary to consider the alternative measures which were at our disposal for treating the canal; all of which were comprised in an attempt to restore the original canal. In many old hernias, however, there was in fact no longer any canal. The internal ring was dragged down until it overlapped the external, and there remained simply a hole covered on one side by the peritoneum, and on the other by the skin and subcutaneous fascia. There was a complete absence of the valvular arrangement of the sides met with in the normal canal, and while many surgeons had attempted to restore this valve-like arrangement, they had always failed. Now, if we could not restore the canal, some alternative for this must be sought; and this formation of a plug of cicatricial tissue for supporting the peritoneum seemed to him a most excellent device.

Dr. Gerster, while expressing great admiration for the McBurney operation, thought it was as yet too soon to decide as to its permanent value; time being the only test for such procedures. In many old cases of hernia, with widely dilated ring, he did not consider it necessary to slit up the anterior wall of the canal, as he believed that the upper part of the sac could be reached sufficiently well without this.

Dr. Abbe said it was perfectly true that we were obliged to leave the question of radical cure to time, but nevertheless he thought surgeons ought in the meanwhile to express their opinions in regard to the various methods advocated. During the past year he had performed Dr. McBurney's operation in seventeen cases, and he felt entirely convinced that it was the best that was now at command. In all he had operated in 117 cases, and fifty-two of these were by Macewen's method,

by which he had been greatly attracted. Macewen claimed that other operators did not succeed with it as well as he himself because they did not operate in the right way; but if the procedure was so difficult that no one but Macewen could perform it properly, it was scarcely worthy of the confidence of the profession. He had now abandoned all other methods for Dr. McBurney's, and one of the greatest advantages of the latter he considered its simplicity in general practice. He had not as yet, however, felt willing, like Dr. McBurney, to leave his patients without a truss after the operation.

A considerable number of other speakers also took part in the discussion. In concluding it Dr. McBurney said in regard to the test of time that no results could, of course, be claimed if it were said arbitrarily that we must wait ten years before deciding as to the validity of the cure in any given case. While, however, longer time was certainly to be desired, he thought we could at least study the principles that ought to guide us in such operations. He had not, with a single exception, refused to operate in a single case; the exception being an old man suffering from advanced Bright's disease and in a generally broken down condition. In every case except the one in which the relapse occurred he was quite satisfied that the sac was completely obliterated and the peritoneum rendered smooth. As to omitting to split the canal in certain old cases where the ring might be perhaps 2 inches in diameter, as suggested by Dr. Gerster, he claimed that even in this class of cases the sac could not be obliterated unless the canal was slit up so that the ligature could be applied at the highest possible point. Although he hoped for the contrary, it might be that in the course of time some of his cases would relapse. Up to the present, however, with the exception of the one mentioned, he had failed to find any evidence of threatened or commencing recurrence in any of them.

At the last meeting of the Section on Obstetrics and Gynecology of the Academy Dr. W. Gill Wylie, who is widely known as one of the boldest and most successful operators among American gynecologists, read a paper on *Surgical Treatment of Retroversion of the Uterus with Adhesions, with a New Method of Shortening the Round Ligaments*, in which he expressed views which not very long ago would have been very generally pronounced as decidedly "advanced," but which have of late been steadily gaining ground among many of our most able specialists in this department. Dr. Wylie believes that in nine cases out of ten where there is retroversion with adhesions the tubes and ovaries are diseased, and consequently, that any treatment which does not involve the uterine appendages, if these are diseased, is not only useless but dangerous. He expressed himself strongly on this point because

he finds that many still treat such cases with pessaries, and that even quite young teachers of gynecology still practice and teach the use of the uterine repositr, an instrument that for many years he has considered obsolete and dangerous, since by opening the abdomen it has been found that in the vast majority of instances retroversion with adhesions means salpingitis, local peritonitis, etc., and it is now known why, as a result of trying to break up adhesions years ago, such patients had so many attacks of so-called cellulitis.

While in some cases the ovaries and tubes are not involved, he said we could not in all instances be sure of this without performing laparotomy, and when the abdomen has once been opened, he has devised a simple and efficient way of fixing and holding the uterus forward. Having freed all adhesions, he catches up the round ligament, at a point about midway between the fundus of the uterus and the pubic bone, with a pair of pressure forceps, pulls it up through the abdominal wound, and with a scalpel scrapes the peritoneum on the inner side of the ligament, so as to make it raw. He then folds together the two halves of the ligament and brings them in close apposition by means of two or four strong silk ligatures passed around and slightly into the ligament, so as to hold the folds of the latter firmly together, but not using sufficient force to cut into or destroy the ligament. Afterwards he may make still closer apposition, if this is indicated, by means of finer and more superficial sutures. These steps are then repeated on the other round ligament, and the wound closed.

This procedure, he states, is easily carried out, and if the sutures are not placed deep enough to injure the bladder or include a ureter, he considers it about as free from danger as an exploratory incision. He thinks it is much to be preferred to the so-called hysterhaphy, and is much better than Polk's suggestion to close the abdominal wound and do Alexander's operation after healing up the adhesions. Dr. Wylie has done this operation for the past three years and with excellent results in some cases, and he says that long before this, when removing the tubes and ovaries, he so included the round ligament in his pedicle ligature as to shorten it and sustain the fundus forward.

At the February meeting of the New York County Medical Association formal addresses were delivered by Dr. J. R. MacGregor, the retiring President, and Dr. C. S. Wood, President-elect of the Association. The former was mainly devoted to the consideration of the relations of medical science to the various interests of the community, the advancement of the standard of medical education, and the advantages to be derived from active work in medical societies; while the topic proper of the latter was the *vis medicatrix nature*. This Dr. Wood believed to be for the

most part a delusion and a snare, and, denouncing the so-called expectant plan of treatment of disease, he stated that his faith in drugs had only increased with his experience in practice. A portion of the address was taken up with suggestions for increasing the efficiency and scientific work of the Association.

P. P. B.

MISCELLANY.

MEDICAL GRADUATES.—Following are the numbers of graduates of medical schools that have closed the session of 1888-89: *Ensworth Medical College*, St. Joseph Mo., 9 graduates; *Michigan College of Medicine and Surgery*, 11; *Medical Department of the University of Louisville*, 128; *Medical College of Indiana*, 27; *Southern Medical College*, Atlanta, 50 (?); *Medical Department of Georgetown University*, 14; *Medical College of the State of South Carolina*, 25; *Medical Department, State University of Iowa*, 43; *Miami Medical College*, 12; *Medical College of Ohio*, 85.

THE LACAZE PRIZE of 10,000 fr. has been awarded to Dr. Malassez, Director of the laboratory of histology of the College de France, for his work on tuberculosis.

PUBLIC MEDICAL LIBRARIES.—In the proceedings at the reception given to Dr. Oliver Wendell Holmes on the occasion of his presenting his library to the Boston Medical Library Association, Dr. R. M. Hodges, president of the Association, gave some facts regarding the public medical libraries of this country. "First," he said, in point of time, is the library of the Pennsylvania Hospital, founded in 1760; second, that of the College of Physicians, in Philadelphia, founded in 1788; third, the New York Hospital library, in 1796, etc. Of course, the library of the surgeon-general's office has surpassed in size all these, having a large annual appropriation and a magnificent librarian. Next in rank comes the library of the College of Physicians; next, that of the Academy of Physicians; and our library comes fourth in rank. After that come the Medical Department of the Public Library of Boston, and the New York Hospital Library. In other words, although the youngest of the seven libraries, ours has already passed three of them. We have nearly twenty thousand volumes."

A DOCTRINE OF PUBLIC POLICY.—Another legal decision of interest to physicians has just been announced in this city, and as it is the first of the kind coming before the courts, and will now be accepted as a precedent, we hasten to give our readers the benefit. The suit was brought to recover fees for consultation rendered by a physician while at a distance, the consultant in the case being the patient's own regular attendant, while the temporary attendant was a physician unacquainted with the previous ailments, and asked the regular attendant for advice in the matter as the patient's case assumed a grave form. The patient died at the end of three weeks, during the absence of his sister, his only surviving relative, who was at the time travelling on the continent of Europe. As residuary legatee, the sister not only refused to pay the consultant's fees, but roundly abused both him and his confrère, and like many other doctors, there was nothing for him to do but to bow himself out and enter his claim for collection according to law.

At the adjudication of the case before the Orphan's Court, counsel insisted that although the patient may not have been competent to decide as to the need for consultation during his illness, he was in such a condition when the attendant first saw him, and the auditing judge de-

cided that the consultant having no contract to show was not entitled to recover, as the physician first called had no authority to employ him. An appeal was taken, and on the first of the present month an opinion was delivered by Judge Ashmun, reversing the decision of the auditing judge, and allowing the amount claimed on the ground that it was the doctrine of public policy. The judge said: "If the right, in the consulting physician, to compensation for his services, is without legal merit, then the law is a reproach to conscience. That it has not been passed upon hitherto means nothing, or rather, it means that it has never been questioned, any more than the right of the physician to charge his patient with the drugs he has purchased, or the nurse he has hired for him, when drugs and nursing were indispensable to his recovery."—*Medical Register*.

THE PORTER COUNTY (IND.) MEDICAL SOCIETY recently met at Valparaiso and elected officers as follows: President, G. W. Arnold; Vice-President, A. P. Letherman; Secretary, D. J. Loring.

THE BIRMINGHAM (ALA.) ACADEMY OF MEDICINE held its regular monthly meeting on March 6. The officers of the Academy are: Dr. C. B. Richards, President; Dr. J. G. Orton, Secretary; Dr. W. A. Moore, Treasurer. The Academy was established in 1854. Nearly all of the charter members are now dead. Dr. Orton has officiated in the capacity of secretary from the time the society was organized until now. The next meeting will be held on the Third Thursday in April.

THE CINCINNATI ACADEMY OF MEDICINE elected the following officers on March 4: President, Dr. William Judkins; first Vice-President, Dr. George W. Ryan; second Vice-President, Dr. W. S. Christopher; Recording Secretary, Dr. Geo. A. Frackler; Corresponding Secretary, Dr. J. M. Withrow; Treasurer, Dr. Geo. E. Jones; Librarian, Dr. David De Beck; Trustees, Dr. S. G. Highway, Dr. Giles S. Mitchell, Dr. C. D. Palmer.

THE NORTH-EASTERN KANSAS MEDICAL ASSOCIATION met at Holton on March 6. The attendance was good and the exercises interesting. The next Meeting of the Association will be at Whiting the first Tuesday in June.

SEXUAL CAUSES OF INSANITY.—The Medico-Legal Society of New York has appointed a committee to consider this subject. It is composed of Clark Bell, Esq., President of the Medico-Legal Society; Dr. P. Bryce, Superintendent of Insane Asylum at Tuscaloosa, Ala.; Alice Bennett, M.D., Superintendent of the Pennsylvania State Hospital for Insane, at Norristown, Pa.; Dr. C. A. Rice, Superintendent of Mississippi State Hospital for the Insane, at Meridian, Miss.; Ex-Governor Hoyt, of Philadelphia, Pa.; and E. W. Chamberlain, Esq., of the New York Bar. This committee will be glad to receive the views of alienists, superintendents of asylums, and others as to the question: "How far is Insanity due to Sexual Causes?" Dr. Bennett will read a paper upon this topic before the Medico-Legal Society of New York on March 13.

DR. H. R. STORER, Newport, R. I., Chairman of the Committee of Arrangements of the American Medical Association, has recently received the diploma of associate membership in the Archeological and Geographical Society of Pernambuco, Brazil.

THE AMERICAN MEDICAL ASSOCIATION.—One of the events of the coming season will be the fortieth annual convention of the American Medical Association, which will be held here the last week in June. The last meeting of this Association occurred at Cincinnati in June last, when nearly 1,500 physicians from all parts of the country were present. In addition to this large number, many of whom bring their families, there were upwards

of 100 exhibitors of instruments, medical preparations, invalid appliances, prepared foods and the many other industries connected with the medical profession. The Association includes the leading doctors in regular practice, college professors, hospital surgeons, etc., throughout the country, and is modeled after the great British Medical Association. It will meet this year for the first time outside of the large cities. The Association comes to Newport without solicitation on the part of the local physicians, and under favorable conditions the holding of the convention here will be likely to give the city a boom both as a winter and as a summer resort. To ensure the success of the convention the local committee, which includes all of the resident physicians, with Dr. Storer as chairman, is working earnestly and feels confident that the visitors will have no reason to regret their selection of Newport. It is possible that the City Council or a citizens' committee will assist in the entertainment of the visitors, Mayor Coggeshall having suggested such action to the City Council, in connection with the observance of the 250th anniversary of the settlement of the city.—*Newport News*, February 27.

NEW YORK MEDICO-LEGAL SOCIETY TRANSACTIONS.—The first edition of the volume of papers and addresses read before this Society, called Series No. 1, having been exhausted, it is proposed to issue a new edition. The volume will contain 600 pp., many papers of permanent value, and will be illustrated with portraits of several distinguished men. The price will be \$3 in muslin and \$2.25 in paper. Persons wishing to secure a copy should send their subscriptions to Mr. Clark Bell, No. 57 Broadway, New York.

CHRONIC BRIGHT'S DISEASE (ARTERIO-CAPILLARY FIBROSIS) IN ITS RELATIONS TO INSANITY.

BY E. A. CHRISTIAN, M.D.,

ASSISTANT PHYSICIAN TO EASTERN MICHIGAN ASYLUM,
PONTIAC, MICHIGAN.

Efforts to frame a satisfactory etiological classification of mental disease have been materially helped by a resort to a clinical grouping of cases. It has been recognized that where a wide variation exists in the causes assigned for the production of insanity in any given series of cases, among certain of them "groups of symptoms" are manifested which point to a definite constantly acting cause. "In many instances we know absolutely that such a cause exists. Even if we do not know that a specific cause is antecedent to the development of a certain form of disease, we are justified in inferring, where symptoms are identical, an identity of cause." Acting upon this theory, it has been possible to frame a rational classification or "clinical grouping" that has simplified much that has hitherto been unsatisfactory and obscure. In spite, however, of the material assistance thus afforded, the lack of a definite pathological basis for perverted mental operations has been keenly felt by alienists.

That constitutional disease has been a comprehensive factor in the production of insanity has long been recognized. Many cases of mental disease manifesting similar symptoms, have fallen naturally into such a group. If it were possible to connect certain of these cases with a more definite pathological process, a step would undoubtedly be made towards simplifying our knowledge of the subject. We are led to believe from clinical observations, and from an interpretation of recent pathological researches in Bright's disease, that we may arrive at a material pathological basis in the classification and treatment of many cases of insanity which have hitherto been set down, rather vaguely, to disturbances of nutrition. When properly understood, it seems

likely that such a group may be made to include not only many that have already been classed under constitutional disease, but also many cases of the rheumatic, choreic and climacteric groups, as well as a goodly proportion of senile cases. The group under consideration will be found to include many suffering from alienation or impairment of mental faculties who have not possessed an especially unstable mental organization, nor an inherited tendency to mental disease. They may present simply a weakening of the faculties, or more violent perturbation, with controlling delusions systematized or unsystematized.

In the last annual report of the Government Hospital for the Insane at Washington, Dr. I. W. Blackburn, Special Pathologist for the Institution, presents in tabulated form the results of an examination of the kidneys in 263 cases of mental disease. Disregarding 104 cases, in which there was unmistakable increase of connective tissue, regarded by the author as "unimportant," we find 43 cases "in which the deviation from the normal was sufficient to constitute disease, including cases of *senile atrophy* of pathological degree." For present purposes the results are of little importance, in the absence of anything like a clinical history of the cases. Reference is made to them merely to call attention to the relative frequency with which Bright's disease occurs in insanity, either as an exciting cause, or as an accidental complication. Nearly one-sixth of his autopsies presented alterations "sufficient to constitute disease." It is reasonable to suppose that a respectable proportion of this one-sixth were cases in which the mental disease bore more than an accidental relation to the disease of the kidneys.

Out of a total of upwards of twenty-six hundred admissions to the Eastern Michigan Asylum, 37 cases have been collected in which the appearance of grave disturbances of nutrition have been co-incident with the discovery of albumin and tube casts in the urine. In only about a dozen of these cases could it be said that the mental manifestations were not dependent upon or modified to some extent by the renal disorder. The intimacy of this connection can be better estimated when we come to consider the different ways in which the association may manifest

* Report of Eastern Michigan Asylum, 1882.

itself. The little that seems to have been written on the subject justifies the belief that the importance of the relation between Bright's disease and insanity has not been fully appreciated. Those articles which have come to the writer's notice have not embraced in their treatment of the subject the full extent of the connection between the two pathological processes. It has been treated as if mental disturbance could occur only as a uro-toxic consequence of impaired functional activity of the kidneys; losing sight of those cases in which both conditions may be regarded as an expression of a more widely diffused morbid process. If insanity with Bright's disease occurred only as a uræmic condition the rarity of such conditions would justify the little consideration that has been bestowed upon the subject.

The most recent ideas respecting the nature of Bright's disease, render it easy for us to accept the notion of an affection which rivals syphilis in the multiplicity of its manifestations, acting as an efficient factor in the production of insanity. Regarded as one of the symptoms of the constitutional affection, the mental derangement is as easily accepted as the persistent vomiting, the diarrhœa, or the rarer complications, like chorea and other purely nervous disturbances, mentioned by recognized authorities as occurring in this disease, more especially in the cirrhotic form.

Although pathologists are not agreed as to the seat of the primary lesion in chronic Bright's disease, it is no longer regarded as existing altogether in the renal structure. A brief review of the evolution of present accepted theories concerning its pathology, will help us, I think, in arriving at an understanding of the extent of the relation which may exist between this affection and many cases of mental derangement. Within the past year two contributions to the subject of chronic Bright's disease have appeared which must command attention, not only on account of the prominence of the authors, but also because of the advanced theories presented therein, founded as they are upon original pathological research. The first of these was the Middleton Goldsmith lecture delivered April 18, 1888, by Dr. J. M. Da Costa, on "The Relation of the Diseases of the Kidney, especially the Bright's Diseases, to Diseases of the Heart." The other was a paper read before the College of Physicians in Philadelphia, in June, 1888, by Dr. Arthur V. Meigs, entitled "A Study of the Arteries and Veins in Bright's Disease."

The recognition of increased arterial tension with hypertrophy of the left ventricle was the first fact which tended to place the subject upon a more definite pathological foundation. To account for these vascular changes different theories were advanced, summarized by Dr. Da Costa as follows:

The first view held that renal excrementitious

matter stimulates the action of the heart, leading to its hypertrophy, and that impure blood requires greater force of ventricular contraction to force it through unwilling vessels. This was the view of Bright. A second view (Traube) took account of impurities in the blood, but located the obstruction to the flow, in the vessels of the kidney. A third view (Johnson) suggested that the arterioles refuse to receive altered blood, and that in consequence of their resistance, the *muscular* coats hypertrophy, with consequent hypertrophy of the heart. A fourth explanation asserted a fibroid over-growth of the *outer coats*. While any one or all of these were sufficient to account for the hypertrophy of the heart, they were only suggestive of the probable nature of the disease. When next it was observed that in many cases there was clinical evidence that disease of the heart had preceded the detection of the disease of the kidney, it was thought that congestion of certain internal organs, especially of the kidneys, was dependent upon the former trouble. Finally the demonstration by Gull and Sutton, in 1877, that many cases which had previously been called Bright's disease of the kidney, were, in fact, "due solely to changes having their origin in the arterioles and capillaries, and in the connective tissue in which they lie," led to the abandonment of the idea that the diseased process was a disease of the *kidney*.

The present state of knowledge of chronic Bright's disease is summarized by Dr. Meigs as follows: 1, In cases of albuminuria certain changes take place in the kidney, with which there is commonly associated enlargement of the heart, and sometimes atheroma of the arteries; 2, other changes of a degenerative and atrophic type are found in various organs and tissues of the body, namely, diseases of the cerebral arteries and of the arteries and substance of the spinal cord—described by Gull and Sutton in their paper on "Changes in the Spinal Cord and its Vessels in Arterio-Capillary Fibrosis"—emphysema and slow inflammatory processes in the lung, changes in the heart valves, degeneration of the coronary arteries and of the muscular tissue of the heart, diseases of the liver and the spleen. To account for such wide-spread changes, two schools have arisen; one assuming that the disorder is primarily a blood disease manifesting itself first in alterations in the secreting surface of the kidney; the other maintaining that it has its origin in the adventitia of the arterioles and in the capillaries and perivascular connective tissue.

The late Dr. Fothergill, in his work "Vaso-Renal Change vs. Bright's Disease," attempted to harmonize these views by elaborating a theory of *alarism*, or a reversion to the uric acid formation of lower forms of life, by virtue of which the solubility, and hence, the elimination of excre-

mentitious products, are interfered with. The irritation due to continuous circulation of such toxic matter in the blood results in hyperplasia of the vascular coats, weakening of their walls, and narrowing of the caliber of the vessels.

Influenced by the belief that the pathological process was primarily in the vascular system, Dr. Meigs made an examination of the veins and arteries in a number of cases presenting the complexus of symptoms known as chronic Bright's disease. As a result of his investigations he finds himself able to predict with considerable accuracy that, in addition to the well-known lesions of the heart and kidneys, he will find after death other widely diffused changes. In sections for the microscope from almost every organ, including the brain and spinal cord, he has found an irregular over-growth and thickening of the *intima* of the *arterioles*. He has come to attach little importance to signs which are usually relied upon, almost to the exclusion of everything else, to establish the diagnosis. While the presence in the urine of albumin with casts is positive evidence of the disease, the absence of one or the other does not negative the diagnosis. In one of his cases, in which aortic regurgitation had made its appearance late in life as the result of calcification of the valves, death came on gradually in consequence of heart failure, without dropsy or other symptoms pointing to an involvement of the kidneys, except a trace of albumin without casts when the patient first came under treatment. Microscopical examination after death revealed atheromatous and fibroid alterations in the vessels, and parenchymatous changes in the kidney, with casts in the tubules. He cites also another case in which the autopsy verified the diagnosis, where casts were never found in the urine, although albumin was constantly present.

Da Costa, in his paper referred to above, analyzes 127 cases of valvular disease of the heart, and finds among them only eight cases in which any true affection of the kidney followed the disease of the heart—not one of true contracted kidney—from which he concludes that valvular disease of the heart rarely leads to chronic disease of the kidney. On the other hand, from an analysis of 121 cases of renal disease with concurrent heart disease, it becomes apparent that the character of the kidney affection in the vast majority of cases is that of the contracted kidney. He concludes that "the ordinary valvular affections in the Bright's diseases are the result of the altered tissue-nutrition of the valves, and of the degenerative changes which take place there, as they take place in the large and small vessels of the body. They are favored to a greater or less degree by the morbid products which, from want of proper elimination on the part of the kidneys, circulate in the blood. It may also be a question whether, in part at least, the altered nutrition of the

valves may not be due to affections of their nervous supply." "He goes on to say that while degenerative changes are favored by age, yet age is not the important factor it appears at first sight to be. He has been led to his conclusions by the results of investigations into the condition of the ganglionic nervous system. He has found changes in the cells of a degenerative character sufficient, in his opinion, to account for the vascular changes and for the cardiac hypertrophy. He also admits, with Meigs, thickening of the *intima*, but the primary pathological condition he believes to be in the wasting of the cells of the sympathetic ganglia. This theory, I believe, finds clinical support in those cases in which a patient in his usual health is suddenly overwhelmed by a fatal oedema of the lungs, a rational explanation for which lies in vaso-motor paralysis.

Here, then we have a picture of a disease so generally diffused, that no organ of the body may be said to be exempt from sharing to a greater or less extent in the derangement which may be set up. I am aware that more positive evidence in the form of microscopical examination of the brain substance is necessary to establish the conclusions which I would draw. It should be borne in mind, however, that it is with precisely such cases as we are now dealing that this evidence is most likely to be lacking. Many of them are cases in which the mental disorder has been regarded as a functional disturbance, and whose symptoms are least suggestive of histological changes, and hence, least likely to stimulate to such investigations. It would seem, also, that mental manifestations would be limited to that form of Bright's disease treated of especially by Meigs and Da Costa; but we are little concerned with the nomenclature of Bright's disease, if, as Millard says, "all inflammatory conditions of the kidney arise as a matter of course from the vascular apparatus of the connective tissue."

The same sets of causes commonly recognized as productive of insanity in general, are no less efficient when acting through the medium of such an affection. Dr. Tyson speaks of "mental anxiety, whether the result of grief or of business and financial cares," as among the possible causes in the production of Bright's disease. All authors recognize prolonged mental tension, of whatever kind, as a frequent cause. Adding to this the gradual development of structural changes, whether as an "arterio-capillary fibrosis," or as an increase of connective tissue in the kidney interfering with the elimination of deleterious matter or as both combined, the subsequent appearance of altered mental phenomena is understood with little difficulty, and all the more readily, if we can accept Da Costa's theory of the disease originating in a starvation of the cells of the sympathetic ganglia.

Cases of insanity dependent upon Bright's disease arrange themselves quite naturally into two classes: the uro-toxic, and the vascular, according as the one or the other set of symptoms predominates. The disease is, of course, the same, and the different sets of symptoms may at different times present themselves in the same individual; and, as Meigs has so plainly shown, death may ensue from causes apparently widely diverse, and yet identical lesions be found after death. In the former class are included not only those undoubted cases of uræmic insanity in which the symptoms are of the nature of delirium, the result of blood-poisoning, but also those cases in which the mental perturbation is as much the result of a lowered state of bodily nutrition as of the direct action of poisonous matters upon the nervous centres.

Genuine cases of uræmic insanity have been met with infrequently. The following illustrative case is reproduced from the last biennial report of the Eastern Michigan Asylum. The patient was a female, æt. 34; mother died of consumption; otherwise, family history good. There was no inherited tendency to mental trouble. Patient had puerperal convulsions attending a miscarriage three years previously. She is said to have been insane for some time following. A second attack, also puerperal in causation, occurred two years later. The present attack, likewise puerperal, was of two months' duration prior to admission. During the entire interval between the first and last attacks there was a history of grave dyspeptic disorders, associated with failing vision. Previous to her transfer from home she is said to have been occasionally maniacal, though for the most part confused and restless. At the time of her admission she was greatly reduced physically, and her pulse was rapid and feeble. There was a peculiar tremor about the lips while speaking, and her articulation was indistinct. Her mind was bewildered and her conversation wandering. She had little appreciation of her surroundings. Her urine contained many casts, with much renal debris, and albumin was present in considerable amount. Mental disturbance was of the character of delirium. There were extreme restlessness, picking at the bed-clothes, and low, muttering conversation, but never any maniacal manifestations. She took food poorly, and rapidly exhausted. She died semi-comatose less than a month after her admission to the Asylum. She was not able to express herself coherently at any time during her stay in the institution."

Symptoms attributable to uræmia may appear in the progress of other cases where the earlier mental manifestations point rather to a disturbance of the general nutrition of the patient. A clergyman, a gentleman of intelligence, who was suffering from melancholia of a suicidal type,

had broken down in his work, partly in consequence of continued ill health; partly as a result of natural peculiarities which unfitted him for his calling. For over a year previous to his admission to the Asylum he had been a confirmed invalid, suffering from dyspeptic troubles, headache, frequent vomiting, periodical attacks of eczema, etc. From being merely hypochondriacal, emotional and despondent, he came to entertain active delusions, first, of suspicion respecting his friends, eventually, of personal unworthiness. In spite of a nourishing diet, a quiet mode of life, and remedies directed to restoring his strength, the patient went steadily from bad to worse. Physical prostration progressed out of all proportion to variations of weight, and of force of the circulation. Hallucinations of vision and of hearing came in to intensify his delusions and to make his condition more pitiable. These systematized delusions gave place finally to a low delirium, with complete incoherence of ideas. With all this there were intense excitability of the motor centres, grinding of the teeth, jactitation, and increase of the visual and auditory hallucinations. Towards the close, spasms of all the voluntary muscles recurred frequently. Except that these attacks were not attended by a condition of insensibility, they did not appear to differ much from an ordinary convulsive seizure. He finally passed into a state of unconsciousness in which he died, four months after his admission. His urine, during his stay in the asylum, presented no marked deviations from the normal, either in the amount excreted, or in the specific gravity. Albumin was present in small amount. Hyaline and granular casts and cells in a state of granular degeneration were present in abundance. The patient never had any paralysis nor localized convulsion, nor any symptom pointing to a focal brain lesion. Œdema was never present. Unfortunately, an autopsy was not practicable.

It may not be out of place, to recall here, that the amount of urea found by quantitative estimation to be excreted in twenty-four hours may not be a reliable indication of the presence or absence of uræmia. The daily excretion of urea we know to vary widely, not only in different individuals, but in the same individual, and this variation may be within the limits of perfect safety. On the other hand, we can understand how life may be gravely threatened by all the dangers of uræmia when the amount of urea excreted is found to be nearly or quite up to the standard fixed as normal. The kidneys do their work well up to a certain point, removing all the waste products, except a certain small amount which is left over as a residuum, to be added to daily by small increments. Gradually the point is reached at which these matters cannot circulate in the blood without manifesting their presence; or it may be that after an unusual inges-

tion of nitrogenized food, or an unaccustomed amount of exercise, or both together, the system becomes suddenly overwhelmed. It is obvious that the kidneys of such a person will be least likely to present gross structural changes.

In the following case there can be no reasonable doubt of the dependence of the mental disorder upon the renal disease, or of death resulting from uræmia: A retired capitalist, 81 years of age, well preserved, of temperate habits, and without inherited taint, began to fail in mind eighteen months prior to his admission to the asylum. He became restless, irritable towards members of his family, and unwilling to remain at home. At first he had delusions of extravagance. To these there succeeded, later, periods of noisy excitement lasting for several days, during which he feared robbery and personal injury. Chronic Bright's disease had been diagnosed by his medical attendant a year previous to his coming to the asylum. At the time of his admission he weighed in the neighborhood of 200 pounds. There was no evidence of arterial degeneration, but his pulse was full and slow, and the left ventricle was manifestly hypertrophied. His pupils were contracted, and the urine contained albumin and casts. His delusions gradually lost form and were replaced by confusion of ideas. Later, recurring attacks of vomiting were followed by loss of appetite and flesh. Attacks of dyspnoea occurred occasionally, sometimes attended with expectoration of blood. Slight pitting of the ankles occurred towards the last. This patient finally died in a coma, which persisted through five days.

More frequently the mental symptoms do not suggest uræmic intoxication as much as a general lowering of the nutritive processes. The brain, with other organs, feels the lack of a healthy blood supply. Such cases are apt to accompany or follow a train of dyspeptic symptoms. The patients become low-spirited; sustained mental effort and the pursuit of the ordinary avocations are impossible; the mind dwells upon the bodily symptoms, and confirmed hypochondriasis results. If delusions develop, they are usually confined to groundless ideas of suspicion of friends, or to ideas of personal unworthiness.

As illustrative of chronic Bright's disease associated with this type of mental trouble, the following cases are reproduced from the last biennial report of the Eastern Michigan Asylum: A male, æt. 45; no hereditary tendency to mental disease; had been a temperate man, but there was a history of dyspeptic troubles dating back many years. During the fall preceding his admission he had become peculiar, forgetful and confused. Later, he was nervous and hypochondriacal, and in the winter developed religious delusions, associated with ideas of a self-condemnatory character, and became suspicious

of the different members of his family. He was finally brought to the asylum, partly in accordance with his own wishes, with some appreciation of his condition. He had complained of failing vision for two months. Upon admission he seemed reduced physically. Pulse 102, and weak. He continued despondent and hypochondriacal, and was at times distressed by his delusions. Casts and albumin were present in his urine from the first. On several occasions he experienced seizures which were regarded as of uræmic origin; complained also of seeing balls of fire. After one of his seizures his attendants thought he was dead, and resorted to artificial respiration to restore him. He remained confused and more or less insensible to his surroundings during the rest of the day, and on recovery, articulation was noticed to be very indistinct. Bed-sores developed, and towards the last suppression of urine occurred. Diarrhoea was a troublesome feature. He died semi-comatose four months after admission.

A female, æt. 57. Family history good. Patient was naturally of active habits, cheerful and amiable. Mental failure followed close upon a continued fever of some sort, two years and a half previous to admission to the asylum. Health had never been good since. Mental peculiarities were at first confined to causeless worrying about her children. Later, she became profoundly depressed and labored under delusions of suspicion of those about her. When admitted she was in feeble bodily health. Lower extremities were extremely cedematous, and urine contained albumin and casts. There was present as an almost constant symptom a considerable degree of bronchial irritation. There was persistent cough, with paroxysmal seizures of an asthmatic character. She became very asthenic, and finally died, as the result of pleural effusion, four months after her admission.

While the assumption of a uræmic origin seems the most natural explanation for many of the symptoms in the foregoing class of cases, there are other cases in which the prominent symptoms are manifestly of vascular origin. In the writer's experience this class has been the more numerous. In a paper read before the meeting of the American Neurological Association, in 1888, on "The Relation of Renal Diseases to Diseases of the Nervous System," Dr. Robert T. Edes belittles the importance of uræmia as an element in any of these cases. He denies that symptoms generally associated with acute and chronic Bright's disease, such as headache, sensory disturbances, dyspnoea, paralyses, neuralgia, itching, eruptions, etc., are uro-toxic. On the other hand, since many of the typical "uræmic" symptoms are wanting in these cases of insanity, he concludes that interference with the eliminating functions of the kidneys is not sufficient to account for all

the symptoms presented. He calls attention to the fact that so-called attacks of uræmia, in the midst of apparent health, are most common in the interstitial variety of Bright's disease, where the vascular element in the disease (by which he means high arterial tension, associated with hypertrophy of the left ventricle) is most common; and not that form in which the epithelium is chiefly involved. It must be borne prominently in mind that the disease, as described in the researches of Meigs and DaCosta, is primarily vascular, with secondary changes in other organs, of which the kidney lesion is but one. Not all patients suffering from this vascular fibrosis manifest mental perturbation, for the same reason that all do not present casts in their urine. As the changes are more advanced in one or the other organ, so will the functions of that organ be the more interfered with. In some of the cases which have come under observation the symptoms have at first suggested a possible organic brain disease, and have borne no slight resemblance to paralytic dementia. Delusions of an extravagant type have been met with occasionally. In a number of cases of mental decay following paralysis, there can be little doubt that the cerebral lesion was but an incident in the vascular changes of the Bright's disease. Dr. Edes dwells upon attacks of paralysis appearing a short time before death. He demonstrates, I think, that a rise in tension in the blood-vessels of the brain, either from spasm of the walls of the vessels, or from the violence of the impulse of the hypertrophied heart, is more likely to be the cause, than a sudden diminution in the amount of matter excreted by the kidneys. If instead of a localized œdema, with subsequent reabsorption of the effusion and disappearance of the motor disability, a rupture of the vascular coats occurs, there results a lesion of which vestiges remain during the entire subsequent progress of the disease. It is not unlikely that further investigations will enable us to include a larger number of cases of "dementia with paralysis" in this class. The three following cases are cited to illustrate this point:

A male, æt. 45. Father said to have died of paralysis. He was an industrious and hardworking man, and had attempted to manage a farm during the daytime and to carry on his trade (that of a shoemaker) at night. Two years previous to his admission he was stricken with left hemiplegia. Mental failure dated from this attack. He lost judgment, became confused, and developed delusions of suspicion. At the time of his admission to the Asylum there was marked arterial tension, with increase in the area of precordial dulness. During his stay in the Asylum many of his symptoms strongly suggested paresis. There was thickness of articulation and much muscular incoördination. Frequently occurring attacks of diarrhœa were a troublesome feature. Towards

the latter part of his life he became very dropsical. Albumin and casts were found in his urine. He finally died in consequence of a pleural effusion, not quite four years after his admission to the Asylum. A post-mortem examination showed both kidneys to be atrophied and cystic. The heart, otherwise healthy, was enormously hypertrophied—weighing 22 ozs.

A male, æt. 65, a sailor; was known to have been licentious and intemperate, although no history of specific infection was obtainable. He was first admitted to a United States Marine Hospital, suffering from the effects of a left hemiplegia. His mental condition rendered it impossible to obtain from him any information as to the duration of the paralysis. During the six months of his stay in this Government Hospital he demented rapidly, becoming finally so restless and noisy as to render his transfer to the Asylum necessary. At the time of his admission his arteries were in an advanced stage of atheromatous degeneration. There were contractures and wasting of both the arm and leg on the left side. He was at first unable to express himself, but later he improved so as to make his wants known, and acquired a fair appreciation of his surroundings. His vision, which was imperfect from the start, failed progressively. He repeatedly sustained "seizures" marked by sudden and complete loss of consciousness, without accompanying interference with the heart's action. His attacks were accompanied by vomiting, but never by convulsions. Later, diarrhœa became a troublesome feature. Bed-sores developed, emaciation progressed, and vision became nearly abolished. His urine contained albumin in moderate amount and granular casts in abundance. He finally died in coma, nine months after coming to the Asylum.

The third case occurred in a man of exemplary habits, and without any inherited tendency to mental trouble. A little over two years prior to his admission to the Asylum he suffered an attack of paralysis. According to the account given by his physician he fell from his chair and remained unconscious for eighteen hours. The attack was accompanied by slight convulsions during the first few hours. There were stertorous breathing and great congestion of the head and face. Twice afterwards he had a similar attack; the last time six weeks previous to his admission to the Asylum. The last two attacks were similar to the first, but without convulsions or loss of consciousness. The paralysis does not seem to have been strictly limited to either side. His mind commenced to fail shortly after the first attack, and progressed rapidly during the interval between the last attack and his admission to the Asylum. His mental symptoms were chiefly those indicative of decay of the mental powers. Delusions were not present at any time. At the time of his admission to the Asylum he weighed 193 lbs., and presented

the appearance of being well nourished. There was marked arterial tension, with increase of the area of precordial dulness. No heart murmurs; no evidence of atheromatous degeneration; pupils normal; vision very imperfect, and could not be remedied by glasses. His gait was very paretic—equally so on both sides, and hand pressure was greatly diminished. There was some anaesthesia. The urine contained albumin and a few small hyaline casts. Dropsy was never present, even in small amount. His stay in the Asylum was marked by no special mental symptoms, occasional attacks of bewilderment being the most prominent mental manifestations. Less than a month following his admission a sudden oedema of the lungs overwhelmed him, and he died, within two hours, of suffocation. This oedema of the lungs was accompanied by several profuse watery discharges from the bowels. For several days previous to his death he had complained of constant and severe headache. He had become accustomed to brief attacks of dyspnoea coming on after rising in the morning.

“Insanity of Bright’s disease” is not meant to designate a new form of mental disease. However, as indicating a probable origin of many cases hitherto not fully understood, it is an admissible term. It offers indications for temporary relief, establishes a prognosis in certain cases which, but for the presence of albumin and casts, might offer delusive hopes, and provides an explanation for the persistent downward course of many cases which have the outward appearance of uncomplicated cases of melancholia.

In conclusion, I present a brief summary of what I have attempted to consider in the foregoing pages.

1. The frequency with which evidences of chronic Bright’s disease are found associated with mental derangement leads to the belief that the latter condition is often dependent upon the former as its cause.

2. This belief finds support and explanation in the present accepted ideas of the pathology of chronic Bright’s disease, according to which the disease is no longer regarded as confined to the kidneys, but as possessing features which make it essentially vascular. These consist in structural alterations in the blood-vessels of the brain and spinal cord, as well as in the vessels of other organs of the body.

3. There are cases of insanity with chronic Bright’s disease which are of uro-toxic origin, but in the majority of cases the mental manifestations must be regarded either as an expression of lowered nutrition or, as is more frequently the case, due to vascular changes in the brain, attended often by convulsions of other than uræmic origin; disturbances of speech and of locomotion.

4. Finally, in many cases of dementia with paralysis it will be found that the destructive brain

lesion, with subsequent decay of the mental faculties, is the result of an alteration in the vascular coats of the brain, coexistent with an hypertrophied heart, and with structural changes in the kidneys.

ON THE MICROSCOPICAL DIAGNOSIS OF CANCER.

*Read before the Medical Society of the District of Columbia,
November 28, 1888.*

BY EDWD. M. SCHAEFFER, M.D.,
WASHINGTON, D. C.

Cancer is a disease which is, unfortunately, but too common in all parts of the world; and whether, as some have asserted, there is a higher percentage of deaths from this cause in the District of Columbia and the adjoining States than elsewhere, or whether there is a tendency of these cases to gravitate hither from other portions of the country, certain it is, that the records of our Society, as well as the vital statistics of the District, show that we have at least our full proportion of deaths from this disease. To the theories as to its cause I shall but briefly refer, leaving also the practical subject of treatment to the physician and the surgeon.

A somewhat particular study of morbid growths, extending over upwards of twenty years, and observations founded on many microscopical examinations, as well as such clinical notes as I have recorded in my note-books, wherever such were obtainable, would seem, however, a sufficient basis upon which to offer some practical points which may be of advantage to the general practitioners, as well as to the surgeons included in the membership of our Society.

The minute structure of malignant growths has always attracted the attention of the most eminent pathologists, ever since the improvement of the microscope has enabled them to be studied under a magnifying power sufficiently strong to give those details of cellular structure on which their classification in modern pathology is founded. To a certain extent this classification has given us results in harmony with the clinical history of such growths, and been of practical use to the physician, whom it enlightens on obscure cases of internal growths, often enabling him to make a correct diagnosis when other signs fail, in such cases as afford an opportunity for the study of the morbid products expelled by the natural outlets of the body. When these chances do not occur, it is but too often, it must be admitted, that it only proves of *post mortem* benefit to the patient and his friends, in ascertaining after death the exact nature of the disease. Even here the aid of the microscope is frequently invoked, and clears up many otherwise doubtful cases of diagnosis where the unaided vision would leave the case in uncertainty, and the practical advantage

in the diagnosis of future cases presenting similar symptoms is not small.

In the majority of cases of external cancer of pronounced types, and especially in epithelioma, we are able to make the diagnosis with much precision, and a prognosis based upon such results is of a high degree of certainty. The surgeon is encouraged to act boldly where an operation is practicable, and the patient is induced to submit to an operation the arguments in favor of which might otherwise fail to carry conviction.

But there are some forms of morbid growth resembling in some particulars malignant disease in structure, where the natural history is widely different from that of the true malignant types, and in spite of the elaborately illustrated works on the subject, the physician will frequently come across forms not distinctly referable to any of the classified types. This is to be expected, because we now know that cancer is not, as was formerly supposed, an entirely foreign and separate entity, having its seat among the healthy tissues of the body, from which it draws nourishment while it destroys them, but rather the cellular manifestation of certain modifications produced in previously normal tissue by a process of disease not apparently governed by such well-defined and definite laws as would lead us to expect uniformly similar results in similar growths observed in different cases.

The possible production of cancer by a minute parasitic form of a vegetable nature has recently been again discussed, and though the omnipresent microbe has not yet been traced to its lurking-place in this disease, there is much plausibility in the theory of such an origin for benign as well as malignant growths.

The curious distortions of leaves, flowers, and other parts of the plant under the irritating influence of insect punctures, and the tumors and hypertrophies of limbs of trees and shrubs evidently due to extraneous causes at first, cannot fail to suggest to the student of nature a certain analogy to similar distortions in the animal structure, which, while it may be fanciful, is possibly a suggestion of a somewhat similar cause in both, modified in its results in the animal by its differing and more highly organized systems of nutrition and growth.

As far back as 1854, a member of the Royal Microscopical Society of England, Mr. Jabez Hogg, in his work on the microscope, expressed a belief in the "fungoid origin of cancer." But taking our knowledge of the structure of cancer as it stands, the question arises whether, in spite of the acknowledged ability of the microscope to distinguish its principal types, the surgeon is using that instrument to the extent of its power in diagnosis. Whether in fact, disgusted by a few contradictory results, he is not inclined to consign it to the category of wholly unreliable tests? While

but few are willing to put themselves on record to this effect, the less guarded private utterances of some of our own members would seem to indicate such an opinion.

Let me briefly advert to the causes which I believe have induced this mental attitude on the part of some members of the profession. In the first place, as some one (Huxley, I believe), has remarked, the value of microscopical observations depends much more on the quantity and quality of cerebral tissue *behind* the visual organ of the observer, than it does upon the excellence of the lenses *in front* of that expressive feature. Some men seem never able to acquire the faculty of intelligent and discriminating observation. But this should no more discredit true microscopical work than the erroneous observations of early writers in ascribing certain diseases to microscopical germs, as malarial fever to the Palmella, for instance, should be used as an argument for the fallaciousness of all later work by other observers in the same direction. And it would be illogical for the surgeon to take the ground that because the electrical indicator gave erroneous results in the localization of a metallic missile in the case of President Garfield, therefore all future appliances of electricity as a guide to the surgeon in doubtful cases should be condemned.

Really good observers are sometimes overawed, as it were, by a previously announced diagnosis by men of high reputation, to the extent of modifying their own observations to accord with the weight of opinion among those who have viewed the case from an entirely different standpoint. The result is apt to be a sort of composite opinion, from which all true original judgment has been eliminated. But I take it to be the function of the microscopical observer, when appealed to in doubtful cases, to ignore all collateral evidence as much as possible, and pronounce an opinion independently of any other considerations on the case before him. Whenever I have allowed myself to be thus biased it has subsequently proved that my judgment would have possessed more value if entirely free from such influences, and it has been my habit for years, when called on to examine a case of suspected disease, whether cancer or other morbid process, to request that all information as to the case be withheld until I have written my opinion. Another advantage of this method is, that whereas the human memory is often treacherous, the *littera scripta manet*, and the possession of written copies of all opinions, has been of value in case the loss of the copy given the patient or his medical adviser might lead to dispute as to what such original opinion had been. After this has been done I endeavor to obtain for my notebook all points of peculiar interest in the case, and the final result whenever practicable.

I have in my cabinet sections of a thickened band of the mucous layer of the rectum in a case

in which the patient had procured the opinions of eminent surgeons in this city and New York. The identical piece from which my sections were made had been examined microscopically by different pathologists, and pronounced epithelial cancer. One of the observers who gave this opinion was the author of a valuable work on the diseases of the rectum. Yet this was a case where a thorough acquaintance with the normal structure of the part seemed to justify my opinion given in writing to the patient, that there was not a single spot in the section which could not be duplicated from a section of the normal rectum, a hypertrophy and somewhat abnormal position of the mucous follicles of the part having however produced in the sections an appearance somewhat resembling certain forms of glandular neoplasia, but certainly *not* the structure of epithelioma. The sections on which I based my judgment were, some of them, submitted by the patient to several expert microscopical diagnosticians in Baltimore and elsewhere, who without being informed of my opinion already given, coincided in their judgment of the case with the view taken by me. Had I been previously acquainted with the array of surgical talent that had pronounced the case one of cancer I might have been frightened out of my diagnosis, yet the patient, who had no doubt for some time carried the growth which was first submitted to me in April, 1886, has since been perfectly restored to health, after a not radical operation by electricity as I have been informed, and when last heard from had experienced no return of the growth.

This case serves to illustrate the importance of another requisite in microscopical diagnosis, for want of which the best powers of observation and the most cultivated judgment will sometimes fail, viz., a sufficient experience not only with morbid growths, but with all the normal tissues of the body. No one can be reliable as a pathologist in the study of the more evident changes which the unaided eye detects in disease, unless familiar with all the variations in health. This seems a truism, yet it is apt to be lost sight of in the applications of the microscope. A section through a Paccinian or tactile body in the finger of an infant, perfectly normal, was once submitted without remark to a microscopist, who unhesitatingly pronounced it to be epithelioma. Yet, the gentleman whose more particularly pathological studies led him to pronounce this opinion, was an eminent observer, so eminent that the ingenious youth who had interrogated him, being an official subordinate, was afraid to inform him of his error, and he never consequently derived the due benefit from that object lesson.

Besides a knowledge of normal tissues, the observer should be familiar with the changes produced by simple inflammation, hypertrophy, lesions of particular diseases, such as syphilis,

etc. An acquaintance with the modifications due to chemical re-agents is sometimes useful, as well as considerable experience with vegetable and other extraneous structures, when discharges supposed to be from the bladder, uterus, etc., are searched for indications of cancer. Altered membranes and clots from the uterus are often of a very puzzling description, and without much familiarity with these discharges serious error may arise.

A rock on which many observers are wrecked is the improper selection by the surgeon of the portion of tissue to be examined. For fear of taking too much tissue, a small piece may be excised which on examination will show the effects of inflammatory induration, or hypertrophy of the part such as commonly occurs in the neighborhood of malignant growths and yet no true cancerous structure be included. The diagnosis is correctly made, but upon imperfect data, and the result is that the microscope, in common parlance, gets "a black eye" as an instrument of accuracy in diagnosis. In other instances a growth which in its initial stage has not fully attained the structure of carcinoma, if not removed, may subsequently proceed to develop its typical character and a diagnosis founded on an early examination be thus discredited.

In conclusion I will briefly relate a case of peculiar interest to me, in which at the first examination of the patient's urine I made the diagnosis of cancer, which has since been confirmed by the subsequent history and an autopsy.

A man, about 60 years old, was sent to me May 4, 1888, by Dr. N. S. Lincoln, for the purpose of having an examination of his urine. Patient was tall, dark complexioned, rather sallow but not cachectic in appearance, said he had pain in his back. Had not yet been examined by Dr. Lincoln, who wished to learn the condition of his urine he said. He sent for report the same afternoon, but it was not completed. The report sent to Dr. Lincoln was as follows:

Anal. 3720. May 4, 1888.—Color of urine natural, nearly clear, moderate amount of deposit, of a whitish flocculent character, moderately acid, spec. grav. 1.014. Quantity in twenty-four hours not stated, but patient had observed no change in that respect of late. Albumin about one-half of volume when coagulated. No excess of phosphates, no sugar, urea not below normal average per oz. *Microscopical examinations:* No casts. No fresh blood, but shreds of fibrin (from blood-clot?). The deposit contained a large proportion of pus, and epithelium from the bladder, and also numbers of large, many-nucleated cells, *not normal*. No crystalline sediment.

In a note to Dr. Lincoln accompanying the report I said: "As this patient was apparently very anxious about his case and might want to see the report of analysis, I write you separately in order

not to needlessly alarm him, to say that there is no doubt in my mind as to the character of the many-nucleated cells, viz., that they are typical cancer cells. If any small clots are observed in his water, it might be well to have him drop them into weak spirits and let you see them."

May 10, 1888. *To Dr. Lincoln*: "I gave Mr. J.'s son the result of the second analysis in his father's case, and see no reason from the microscopical appearances in this analysis to change the opinion of the case formed at first. Absence of local pain and hæmorrhage may indicate a favorable form or early stage of the growth, if one exists."

The case progressed and I made frequent examinations of the urine up to July 18th. The albumin was always found, but diminished in amount ultimately. The color was for some time natural, and no clots or increased deposit to attract the eye, at first, but subsequently the urine became turbid, and the deposit more abundant, and pinkish in color, and toward the last a few blood corpuscles appeared. No casts were found at any time. The urea gradually fell below normal average. The many-nucleated cells were at first all separate and distinct, but in Analysis 3818, July 16th, they were also found in small continuous fragments of tissue, the largest of which were distinctly visible to the naked eye. Death occurred on the 3d of November, and an autopsy was made by Dr. D. S. Lamb.

[The right kidney was found, at the autopsy, to be converted into a cancerous mass, which under the microscope showed the structure of epithelioma.]

A CASE OF PERITYPHLITIS.

*Read before the Medical Society of the District of Columbia,
December 12, 1888.*

BY T. E. MCARDLE, A.M., M.D.,
OF WASHINGTON, D. C.

T. K., male, white, æt. 34 years, consulted me at my office on the evening of November 15, 1888. He complained of general malaise, with localized pain in the lower part of the abdomen towards the right side. He had a short, harassing cough. His bowels had been freely moved from some purgative pills taken the previous night. His pulse was 100, temperature 102.6°. I ordered him home and to bed at once and prescribed codeia and quinine, together with a strict liquid diet.

On the following morning (November 16), I found that he had passed a very comfortable night. A thorough examination revealed a tumor in the right inguinal region. The pulse was 80 and the temperature 100° F. Poultices were ordered. When I saw the patient again in the evening his pulse was 100 and his temperature 102°.

On the morning of the 17th Dr. J. Ford Thompson saw the patient with me. He had enjoyed a

fairly good night and his bowels had moved naturally. The pulse was 100 and the temperature 101°. Pus easily detected. Poultices continued. Evening pulse 110, temperature 103°. On the morning of the 18th the pulse was 100 and the temperature 101°; the patient had passed a comfortable night.

Chloroform was given and laparotomy performed. After the evacuation of the pus, a drainage tube was introduced and the wound was dressed antiseptically. The patient took the anæsthetic badly; the nausea was distressing and the vomiting continued until 3 or 4 o'clock in the afternoon. At 9 o'clock in the evening, when I saw him, his pulse was 100 and his temperature 97.4°. I gave him some whisky and water, which he immediately vomited, together with a quantity of dark-green fluid. A hypodermic injection of morphia $\frac{1}{4}$ gr. and atropia $\frac{1}{150}$ gr. was administered. He spent a very restless night and vomited at midnight after taking a pill of morphia gr. $\frac{1}{4}$ and atropia gr. $\frac{1}{150}$. The fluid was not dark as before. At 10 in the morning the wound was syringed with a carbolic solution, the drainage tube removed, an iodoform tent substituted, and the wound redressed antiseptically. Champagne, milk and lime-water were ordered. Pulse 100, temperature 97.4°.

At 5 in the afternoon the pulse was 96 and the temperature 98.6°. As he had vomited the champagne twice its use was discontinued. At 10 in the evening his pulse was 96, temperature 99.4° in the axilla. He had vomited at 8 o'clock. Suffered from hiccough and had been slightly delirious.

The wound was again syringed on the morning of the 20th and found to be cleaner than on the preceding day. The pulse was 76, the temperature 97.8°. He had had a bad night, as the vomiting and hiccough had continued. He was now better and able to retain a small quantity of champagne. Poultices were ordered. In the afternoon the pulse was 100 and the temperature 99.6°. The wound was syringed and found to be cleaner. An iodoform pad was applied and the poultices were continued. A suppository of morphia gr. $\frac{1}{4}$ and belladonna ext. gr. $\frac{1}{6}$ was ordered.

At 10 P.M. I found that the patient had vomited before using the suppository, but not since. Meanwhile he had slept three hours. He felt much better. His pulse was 88, temperature 98.4°. The iodoform gauze was changed, another suppository ordered, and the poultices renewed. He slept well during the night, but vomited clear fluid at 7 in the morning. At 10 o'clock the pulse was 86, the temperature 97.6°. The wound was cleansed and dressed, and the poultices were continued. A bottle of citrate of magnesia was ordered to be taken in four doses at intervals of an hour each. He retained the first two doses but vomited the others. Whilst I was at his bedside at 5 o'clock in the afternoon he vomited a

pint of greenish fluid. The wound was cleansed and dressed. Two enemata were given by me, bringing away some small hard lumps of faecal matter. He spent a very bad, restless night, and vomited many times. He had another small movement, hard and lumpy.

At 10 A.M. his pulse was 88, temperature 99°. The wound was syringed and the poultices were continued. Three suppositories had been used during the night without producing sleep. A grain of calomel was ordered every two hours until 3 grains were taken.

At 5 in the afternoon the pulse was 92 and the temperature 99.8°. The wound was again syringed; there was very little discharge. He had vomited frequently, twice while I was in the room. The fluid was large in quantity, yellowish-green in color, and bad-smelling. There had been no movement from the bowels, though all the powders had been taken. I washed out the rectum three times with some effect.

At 10 P.M. the pulse was 98 and the temperature 99.4°. The patient had vomited six times, and his bowels had been moved twice. The odor was horribly fetid. A suppository every three hours was ordered. The patient was restless until 2 A.M.; has not vomited since that time. Has had two bad-smelling movements.

At 10 o'clock the wound was cleansed and but little discharge found. Pulse 90, temperature 99.4°.

At 5 P.M. the wound was again syringed. The abdomen was softer, though there was some slight pain on the left side. Slight nausea, but no vomiting since morning. Poultices continued and suppository ordered at 8 P.M. After a good night's rest the wound was syringed at 10 in the morning, and the poultices were stopped. No nausea, but hunger. Takes plenty of nourishment. Pulse 84, temperature 98.6°.

At 5 o'clock the pulse was 100 and the temperature 99°. The patient spent a very comfortable day. A suppository was ordered at night and the patient slept well. The next morning, however, he felt oppressed and suffered from flatus. He had doubtless taken too much food. Ordered poultices to be applied and aromatic spirits of ammonia to be taken in teaspoonful doses. Pulse 80, temperature 97.8°. He spent a restless day; vomited five or six times; had a movement at 4:30 o'clock. He had taken very little nourishment during the day, so I ordered liquid bread. At 6 in the evening his pulse was 84, temperature 99.8°.

Although three suppositories were given him, he spent a bad night and slept but little. He had four dark fetid movements from the bowels and vomited eight times. He began to improve at 4 A.M., and now relished his liquid bread.

His pulse was 100 and his temperature 99.8° at 10 in the morning. The wound was cleansed and found to be filling up from the bottom. His bow-

els were moved twice during the day and at 2:30 he vomited. At 5 his pulse was 110, temperature 101.8°. At 7 his bowels were again moved.

At 10 the next morning his pulse was 96, temperature 98.4°. Feels well, takes plenty of nourishment, and expressed a desire to read the newspaper.

At 5 o'clock his temperature was 101.8°, pulse 106. He had passed an excellent day, and had taken plenty of nourishment. He had not been at all nauseated, and was entirely free from pain. There had been very little discharge from the wound. He used three suppositories and slept well during the night.

At 10 in the morning his pulse was 84, temperature 99°. In the evening his pulse was 100, temperature 101.6°. He slept well during the night, and in the morning his pulse was 84, temperature 98°. I ordered a bottle of citrate of magnesia, and his bowels were moved once before 5 o'clock. At that hour his pulse was 94, temperature 99.6. His bowels moved twice again, and he was restless until 2 in the morning. At 10 A.M. his pulse was 80 and his temperature 98.8.

From this time on, with occasional relapses, he continued to improve.

THE SEGMENT TREPHINE AND AN ASEPTIC TREPHINE.

Read before the Philadelphia County Medical Society, Feb. 27, 1889.

BY JOHN B. ROBERTS, M.D.,

PROFESSOR OF ANATOMY AND SURGERY IN THE PHILADELPHIA POLYCLINIC.

The frequency with which operations are now done upon the skull and brain has made apparent the need of improvement in our instruments for opening the skull. Seven years ago I published¹ an account of my experiments with the surgical engine, as a means of making openings in the skull; and I still believe it an excellent and safe means of effecting entrance to the cranial contents. The chief disadvantages are the expense of the engine and its liability in ordinary hands to get out of order. This latter objection held good at least in one hospital with which I have been associated.

The ordinary trephine, either cylindrical or conical, will probably be used much more frequently, therefore, than the surgical engine; hence, suggestions to improve its character are not inadmissible. The "segment trephine," described in the *Operative Surgery of the Human Brain*,² is, I think, a valuable instrument with which to deepen any portion of the groove surrounding the button of bone to be removed, without cutting along its entire circumference. The skull is often very much thicker in some parts of

¹ Philadelphia Medical Times, 1881-82, xii, p. 206.

² Page 78.

the area of operation than in others, and the ordinary trephine has to be tilted to avoid injuring the cerebral membranes at the points where the skull is thinnest. Tilting is not always easily done when the trephine is large and deeply imbedded in the bone. A "segment trephine," having the same radius of curvature as that with which the operation was begun, enables me to cut deeper, and with great care at any selected part of the groove. The accompanying illustration renders a detailed description of the instrument unnecessary. The cutting edge extends one-third of the circumference, and the centre-pin, not requiring retraction, may be immovably fixed to the head of the trephine. The instrument has no groove in the stem or handle to collect septic matter, and is readily cleaned.

A serious objection to the ordinary trephine is the fact that it is almost impossible to get assistants and nurses to keep the centre-pin, and the tubular stem in which it slides, perfectly aseptic. Indeed, it is difficult, with every intention of perfect cleanliness, to keep the hollow stem of the instrument absolutely clean. I have endeavored to remedy this objection by making the stem solid, and substituting for the ordinary sliding centre-pin a circular block of metal, accurately fitting into the crown of the trephine, with a point upon its lower extremity.

As soon as the surgeon has cut a groove deep enough for the teeth of the trephine to be maintained in position upon the skull, the central block is taken out of the crown of the trephine, and the operation continued as with the ordinary instrument, after retracting the centre pin. Upon the upper surface of the block is cut a shallow slot, into which fits a slight projection from the upper part of the trephine crown. This compels

the block to rotate with the rest of the trephine when the operator is making the first incision into the bone. The trephine itself is made as thin as possible, in order that the groove between the disc of bone removed and the rest of the skull may be very narrow. The button of bone, when replaced, can then be held in position more readily than if the groove is a wide one. I believe that after using a thin trephine, such as this, it at times will be well to stitch the button of bone into position by catgut sutures passed through the periosteum, which may be allowed to remain upon the surface of the disc of bone, and upon the skull adjacent to the trephine opening.

The crown of the trephine must not be too conical, because such a trephine in cutting through the thick skull makes the outer portion

of the incision a very wide one. I am inclined to think that a surgeon of even moderate skill never needs a conical trephine to prevent his plunging the instrument into the brain; a cylindrical one should be just as safe in his hands as a conical one. An advantage in having the crown of the trephine slightly conical, when a large instrument is used, is the less liability of the instrument becoming jammed in the groove. This annoyance not infrequently occurs on account of irregularities in thickness of the skull, especially when a large surface is included in the trephine. It is more apt to take place, I think, when the groove is made by a cylindrical instrument, which does not make the external aspect of the incision wider than the internal.

The weight of the metal handpiece can be minimized by fenestræ, or by making the handle hollow. It is best to attach the handpiece to the stem eccentrically, as suggested by Horsley, since the hypothenar portion of the palm needs a longer lever than the thenar.

This aseptic trephine, it will be seen, is somewhat similar to the safety trephine of Hopkins,³ who suggested the use of a cylindrical block instead of a centre-pin, because of the possibility of the surgeon forgetting to withdraw the centre-pin, and, therefore, wounding the dura mater. His device contained a spring to keep the block thrust forward, and was, therefore very difficult to clean. In fact it was not constructed with an idea to facilitate asepsis, but to prevent careless puncture of the dura.

MEDICAL PROGRESS.

RADICAL CURE OF HYDROCELE OF THE TUNICA VAGINALIS.—BRIGADE-SURGEON SIBTHORPE reports from the General Hospital, Madras:

Twenty-six operations for paracentesis of hydrocele are recorded under the head of minor operations in the senior surgeon's wards last year; in 14 of these a radical cure was attempted, undiluted tincture of iodine being injected in 10 cases, and pure carbolic acid in 4. As far as these small numbers go they show that there is not much to choose between the two methods; both appear equally efficacious in certain cases, and both are generally followed by some local and constitutional disturbance. The carbolic acid, however, appears to be followed by less pain than the iodine, though, with it, pain is by no means absent, as some surgeons would have us to believe.

Of the 14 cases, 9 can be claimed as cures; Case 2, with little local trouble, after six days; Case 5, a double hydrocele (there was a good deal of inflammation), discharged cured on the twentieth day, the left being reduced to the size of a hen's egg, the right smaller; Case 6, having been three times tapped and twice injected, left the hospital with a considerable amount of fluid in the tunica, which completely disappeared afterwards under the use of tincture of iodine to the scrotum; Case 7 was cured on the twenty-second day, the local trouble having been slight; Case 8 left the hospital on the twenty-eighth day, the local trouble having been slight; Case 9 left the hospital on the twenty-fifth day, having had only slight swelling after injection; Case 10 left on the eighth day, with the swelling going down. All these cases were injected with tincture of iodine. Case 11 was tapped twice, and injected with pure carbolic acid; he had a good deal of pain and swelling, with some constitutional disturbance; a small abscess formed at the seat of puncture; this was followed by a sinus, which necessitated his being kept under treatment for a long time. Case 12 absconded a month after the operation, with the swelling going down. Case 14 absconded the second day after the operation, so it was impossible to say what was the result.

There were partial cures in 2 cases, namely: Case 1, after injection with tincture of iodine on two occasions, suffered a good deal from pain and constitutional disturbance; he left the hospital with the part still enlarged thirteen days after the second operation. Case 3 left the hospital on the fifth day after the operation with some swelling remaining. In Case 4 castration had to be performed, as the two injections of tincture of iodine had been followed by failure, and the testicle was found atrophied when the sac was cut into. In Case 13 suppuration following an injection with pure carbolic acid required free incision and drainage, which was eventually followed by a cure. The long time taken in the cure in some of these cases, and the histories of the failures, lead one to question which is the most suitable operation for the cure of old-standing hydroceles, where the tunica is much thickened and very much enlarged. No doubt the treatment by injection is by far the most suitable for moderately-sized and comparatively recent tumors.

I would like to call attention to an interesting paper by Mr. J. S. McArdle, published in the *Dublin Journal of Medical Science* of September, 1887, on this subject. He alludes to the fact that the operation of incision for the radical cure of hydrocele is as old as the time of Celsus, but that it had fallen into disuse, and has been only revived since the antiseptic method of dressing wounds has come into use. He gives the following description of the methods now in use:

Incision (Volkman).—An incision is made from the external abdominal ring to the base of the scrotum, and reaching down to the tunica vaginalis. That membrane is incised along its entire length, and bleeding vessels ligatured. The tunica vaginalis is then washed with a 3 per cent. solution of carbolic acid, and its edges applied to those of the skin by numerous points of fine silk suture; the dressings are then applied. English remarks that it is well to leave the ends of the sutures long, so as to avoid the difficulty of finding them in the swollen tissues when, on the third day, their removal becomes necessary.

Partial Resection (Julliard).—After the skin and tunica vaginalis have been cut, as in Volkman's operation, the redundant portions of the latter are removed and the edges of the remaining portion brought together with fine catgut. A drainage tube is then laid in the wound, up to but not into the tunica vaginalis, and the skin wound closed.

Complete Resection of the Parietal Tunica Vaginalis (Bergmann).—After section of the skin and tunica vaginalis, the latter is dissected off close to the epididymis and testicle. Bleeding vessels are then ligatured, a drainage tube laid in, and the skin wound closed by numerous points of silk suture. In all the operations a 3 per cent. solution of carbolic acid is used for washing the parts. Bergmann claims that sloughing of the tunica

vaginalis, cellulitis, necrosis of the testicle, and scrotal abscess follow injection more frequently than the method of incision or resection. He also states that the method of excision or incision takes very little longer, and gives the following relative dates of healing after the different methods:

Injection.—Billroth, 9th day; Stoltz, 9th day; Weiss, 8 to 9th day.

Incision.—Volkmann, 8th to 10th day; Küster, 14th day; Lister, 17th day; McArdle, 12th to 14th day.

Excision.—Julliard, 10th day; Bergmann, 11th to 12th day; McArdle, 7th–12th day.

The chances of recurrence are much less after entire incision, partial resection, or complete resection, than after injection. Mr. McArdle quotes 315 cases of injection by different surgeons in which the disease recurred in 13 per cent.; 245 cases of incision in which it recurred in 2.4 per cent.; 53 cases of partial resection in which it recurred in 1.9 per cent.; and 22 cases of complete resection in which the disease did not recur. He only recommends these methods for cases in which the trial of injection has been made and has failed. —*British Medical Journal*, February 23, 1889.

A CASE OF ELEPHANTIASIS ARABUM is reported by DR. R. W. FELKIN, of Edinburgh, as follows: On the 14th of July, 1888, I was asked to see an unmarried lady, a Eurasian. Her age was 33, her height 5 feet 2 inches, and her weight 11 stones 4 $\frac{1}{4}$ lbs. She was born in India, and had resided there most of her life. She had always enjoyed good health, with the exception of suffering now and then from intermittent fever. She had led an active life, and had apparently undergone considerable exertion. Up to the beginning of 1887 her appetite had always been good, but she had been remarkably thin. After a rather severe attack of fever early in 1887 she noticed that she commenced to increase in size, and that her appetite was capricious. She took a great dislike to fish, and always vomited after eating it. She had also occasional attacks of nausea and vomiting with headaches. Every now and then her occupation became rather tedious to her, and she sometimes felt as if she could hardly keep up. In September, 1887, as she felt gradually growing worse, she decided to leave India for a time; and for some unknown reason she was weighed before starting on her journey, and felt surprised to find that she weighed 9 stones 8 lbs. The voyage home seems to have done her good, for when she landed in England she felt better than she had done for some time previously, and this improvement in her feelings continued for two or three months. She noticed, however, that she still increased in size, and that her skin was at times itchy and very irritable. Her limbs, too, felt painful and sore, more so than they had done in India. During the spring of 1888 she was very busily employed,

walking about a great deal; in fact, she told me that she was more or less on her feet from 9 in the morning till 10 at night. In June, 1888, she felt quite unable to continue her exertions. Her arms and legs felt heavy and powerless, her appetite became very bad, and she felt dull, low-spirited and miserable. Her food, too, frequently disagreed with her. At the beginning of July she decided to take a few weeks' rest, and she then came under my care.

On examining the patient I found her to be rather nervous. Her tongue was slightly coated with a brownish-yellow fur; her pulse was 104, full, and almost bounding in character; her temperature was 100°, respiration 24. Her heart and lungs were apparently quite healthy; her liver was slightly enlarged, the area of dulness being 5 $\frac{1}{2}$ inches in the mammary line; the spleen was markedly enlarged, and extended to within 3 $\frac{1}{2}$ inches of the umbilicus. On examining her integumentary system, I found that a remarkable hypertrophy had taken place; this hypertrophy affected the whole of the body with the exception of the head and neck, the forearms and hands, the legs below the knees and the feet, also the anterior aspect of the trunk from 3 inches below the clavicles to the umbilicus, and the posterior aspect of the body between the scapulæ and underneath them. The upper arm measured 36 $\frac{1}{2}$ cm. in circumference at its thickest part on the right side, and nearly 36 on the left; the thigh on the right side at its middle third measured 71 cm., and nearly the same on the left; the calf on the right leg measured 35 cm. in circumference at its thickest part, and that of the left leg the same. There was distinctly less hypertrophied tissue upon the shoulders and beneath the scapulæ, and a deep groove separated the masses of hypertrophied tissue over the scapulæ. There was very marked hypertrophied tissue in the lumbar region and over the lower part of the abdomen below the umbilicus; in fact, it might almost be described as a girdle of hypertrophied tissue, which sank down several inches when the patient was in the erect position. I was, unfortunately, unable to obtain any more detailed measurements, and I much regret that it was impossible to persuade the patient to consent to a proper photograph being taken of her remarkable condition. I reproduce, however, two instantaneous photographs, which may serve to give some idea of her condition after a week's treatment and her state shortly before she left my care. The skin in the regions I have above mentioned was darkly pigmented, and formed a distinct contrast to my patient's natural complexion; it was rough, having somewhat the appearance of the rind of a boiled orange; it was tense, and appeared to be bound down to the subcutaneous tissue; this was especially the case in regard to the upper arms, the two masses of tissue situated below each clavicle, and those over the

scapulæ, but in the other regions of the body the mass of tissue had a certain amount of movement; for instance, when the patient was in the erect position, the masses of hypertrophied tissue which encircled the thighs descended, especially in front, where they completely overlapped the patellæ. On palpation, one experienced the sense of dense, brawny, slightly elastic hardness. The skin did not pit on pressure, or hardly so, but it was slightly painful to the touch. In many places, especially over the buttocks, it was distinctly nodulated, and presented a most typical elephantoid appearance, which appearance was less marked in the upper part of the body. The glands in both axillæ and in both groins were enlarged; in the natural folds of the body there was a slight exanthematous eruption. I examined the blood and the urine frequently during the progress of the case, and also punctured the tissue in various parts of the body, as I thought that at first I might have to deal with a lymphoid variety of elephantiasis; no lymph, however, could be obtained. The amount of urine passed varied from 50 to 70 ozs. in the twenty-four hours; the sp. gr. varied from 1012 to 1025. With the exception of some albumin which was present in the urine for the first three weeks, nothing abnormal could be detected. On one occasion I thought I saw a few ova of the *Filaria sanguinis hominis*, but repeated microscopical examination gave no confirmation. The microscopical examination of the blood gave no results. Menstruation was irregular and slightly painful.

Treatment.—Absolute rest was enjoined, and the patient had a hot bath almost every day. A moderate amount of bland food was ordered, consisting chiefly of milk (the patient could never eat fish; I tried her with it on several occasions, but it always caused nausea and vomiting). The patient was regularly massaged. Commencing with half an hour a day, the rubbing was subsequently increased to an hour and a half, and the constant current battery was applied for twenty minutes each day. A mixture was prescribed containing quinine, arsenic, iron and strychnine, and the bowels were regulated by the frequent administration of aperients. The progress of the case was in every way satisfactory; with the exception of a slight rise in the temperature for six days after the massage had been commenced, all went well. The patient complained of nothing excepting the battery and the pain that the massage gave her during the first three weeks. The massage and battery were discontinued about the 10th of September, by which time the skin had become normal in character—in fact, had returned to its usual condition, and all tension and hard feeling had disappeared. A remarkable diminution had taken place in the circumference of the limbs, the circumference of the upper arms having been reduced to 25 cm., and the middle

third of the thighs only measuring 54 cm. in circumference. The mass of hypertrophied tissue encircling the body had quite disappeared. The patient stated that she felt quite well, buoyant, and fit for work. She could walk with ease and comfort, and by the middle of October she was apparently quite restored to health, and has continued so to the present time. I should perhaps mention that for a week or two after her prolonged rest the patient suffered from slight swelling of the feet and ankles. This condition, however, completely disappeared.—*Edinburgh Medical Journal*, March, 1889.

NEW ANTISEPTICS IN PHTHISIS.—DR. C. THEODORE WILLIAMS, after speaking of the results obtained with phenyl-propionic acid (see *THE JOURNAL* of last week), says:

Phenyl-acetic acid ($C^6H^5O^2$) belonging to the same series as phenyl-propionic acid, resembles it closely in taste, but has a more acid reaction. It dissolves in alcohol 1 in 6, and when thus dissolved is more soluble in water, so that 20 minims of the alcoholic solution is taken up by a small amount of distilled water. The alcoholic solution was given in doses of 10 minims to 20 minims three times a day, under the same conditions as the phenyl-propionic acid, to 19 cases of phthisis.

Nature of Cases and Duration of Disease.—The patients were 14 males and 5 females, the ages of the males varying from 18 to 40, with an average of 29.6 years, and those of the females varying from 14 to 40, with an average of 21 years. There was a great variety in the duration of the disease in these patients, as it ranged from 2 months to five years, the majority having at least one year's symptoms. One was a case of scrofulous phthisis, and one a case with cavities in both lungs and right pneumothorax. One patient, a girl of 18, apparently contracted phthisis from nursing a sister who was in a far advanced stage of the same disease. In two cases pyrexia was present.

State of Lungs.—Nine patients had tuberculization of one or both apices, the right lung being affected in three, the left in three, and both apices in 3. In most cases the tuberculization did not extend beyond one lobe. In 10 patients cavities were present, in 6 the cavity was limited, and the opposite lung free; in 2 others there was excavation of one lung and tuberculization of the opposite one. In 2 patients cavities existed in both lungs, and in one of these patients right pneumothorax had supervened. There were therefore 7 cases of double affection, against 12 of single affection. The sputum was examined for tubercle-bacilli in 15 cases, and these organisms were detected in all in varying abundance. The patients took the phenyl-acetic acid for periods varying from 21 to 89 days, the average being $45\frac{1}{2}$ days, and in no

case did it give rise to any unpleasant symptom. The odor was perceptible in the ward, though never in the patient's breath or in any of the secretions. All other medicines, except purgatives when required, were suspended during the trial of the drug.

General Results.—Thirteen improved, 3 greatly; 4 deteriorated; and 3 remained stationary. The improvement here consisted in gain of weight, strength, and color, and doubtless this was partly due to the diminution of cough and expectoration. The weights of 18 out of the 19 cases were recorded, and these show gain of weight in 12, loss in 4, and a stationary condition in 2; the gain varied from 1½ pounds to 9½ pounds. The losers in weight included the 2 pyrexial cases and the pneumothorax patient, who died later on.

Local Results.—Twelve patients showed an improved condition of lungs, 4 showed a worse state, and in 3 it was neither better nor worse. The improvement consisted of subsidence of cough and reduction of expectoration, with diminution in the physical signs. In the worse cases there was either advance or extension of the disease, or both. Among the "improved" cases 8 were first-stagers, and in 7 of these diminution of physical signs is noted; and 4 were third-stagers. This shows local improvement in eight-ninths of the tuberculization cases, and in only two-fifths of the cavity cases. The effect on the cough and expectoration was very marked, both being reduced thereby. It would thus appear that the phenyl-acetic acid produced very satisfactory results; general improvement taking place in 68.4 per cent., local in 63.15 per cent. On the whole this acid appears to be more successful than its congener, phenyl-propionic acid, as the subjoined figures of the percentages of improvement will show:

	Patients	Improvement.	
		General per cent.	Local per cent.
Phenyl-propionic acid	20	65.0	35.0
Phenyl-acetic acid	19	68.4	63.4

In gain of weight the phenyl-propionic acid cases had the advantage, as 70 per cent. of these gained weight against 66 per cent. of the phenyl-acetic acid cases.

Neither phenyl-propionic acid nor phenyl-acetic acid appeared to have exercised the slightest influence on pyrexia, and this, considering how closely allied they are to antifebrin and other antipyretics, is very remarkable.

It may be naturally asked, did these patients fare better than similar cases treated with cod-liver oil and bitter tonics who were on the same dietary? Cod-liver oil is a food, not a medicine, and so we can hardly pit these new medicines

against it; but as regards the usually prescribed tonics, such as quinine and mineral acids, I question if any of these can show equal results to the above, and I think therefore that these antiseptics merit a fair trial. I would close this paper with the following conclusions:

1. Phenyl-propionic and phenyl-acetic acid promote appetite, digestion, and assimilation in phthisis, and thus cause gain of weight.

2. They are well tolerated in considerable doses by patients for long periods of time.

3. Their influence on the lungs is less marked than their constitutional influence, but phenyl-acetic acid acts more beneficially on the lungs than phenyl-propionic acid, and appears to reduce cough and expectoration.

4. The use of phenyl-acetic acid appears to be more indicated in cases of tuberculization, and that of phenyl-propionic acid in excavation cases, but a larger number of observations are required to speak with certainty on this point.—*Practitioner*, February, 1889.

SALICYLATE OF CRESOL.—At a meeting of the Academy of Sciences PROF. BOUCHARD read a note for Dr. Letzinski, of Bern, on the salicylate of cresol, which is not soluble, and which is a powerful antiseptic. This medicament has, according to the author, given good results in acute rheumatism. As it is possible to saturate the intestines without inconvenience, and as the microbe of cholera appears to have its principal habitat in the intestines, Dr. Letzinski thinks that this substance may be employed with success in the prodromic period of the choleraic attack. M. Bouchard, however, makes some reserve on this last point, for he does not participate in the opinion of those who hope to cure cholera with antiseptics introduced into the intestines.—*Lancet*, February 9, 1889.

NATURE AND TREATMENT OF DIABETIC COMA.—DR. STADELMANN, of Dorpat, in a recent article in the *St. Petersburgische Wochenschrift*, points out the great similarity which seems to exist between the coma of diabetes and the condition produced in herbivorous animals by inducing acid intoxication. Amongst other points, he refers to some analyses by Minkowski, of the gaseous contents of the blood. In the normal condition, the blood of the rabbit contains 25 per cent. of carbonic acid; but when the animal is suffering from artificially induced acid intoxication, the carbonic acid is diminished. Thus, in one instance, Minkowski found it 16.4 per cent. with a moderate degree of intoxication; when the latter was increased, the percentage of carbonic acid fell further, first to 8.8, and finally to 2.9 per cent. In order to compare this with the gaseous changes in the blood of diabetics, he examined the blood of a patient before and during

¹ These drugs are very difficult to obtain. They are prepared by Schuchardt, of Götting, and have been obligingly procured for the Brompton Hospital by Messrs. Burroughs, Wellcome & Co., Snow Hill, E. C., who now supply them.

coma, the carbonic acid being respectively 17 and 3.34 per cent. In order to ascertain whether this diminution of the carbonic acid in the blood was merely due to coma as such without reference to its cause, he examined the blood of a comatose patient, not a diabetic, whose condition was due to meningitis. Here the carbonic acid amounted to 28.2 per cent. The acid existing in diabetes appears to be oxybutyric acid, which in some cases appears in the urine to the extent of something like 3 ounces per diem. Some years ago Dr. Stadelmann found a new acid, which he believed to be crotonic acid, in considerable quantity in certain cases. He now, however, considers it merely a substitution-product from oxybutyric acid.

The indications for treatment supplied by these views are, of course to, combat the acid by large quantities of alkali. Several attempts have been made to treat diabetic coma by injecting into the veins from 1 to 4 ounces of carbonate of soda dissolved in about four pints of water, with a little chloride of sodium. In only one instance, however, has this proved successful, and unless it is done very early no good result can be fairly expected of it. It is found that the urine in twelve hours after the injection is intensely acid. Better results are to be obtained in attempting to ward off coma by giving alkalies freely. Thus, Dr. Stradelmann prescribes about an ounce of tartrate or citrate of soda dissolved in about half a pint of soda-water two or three times a day, and has found great reason to be satisfied with this line of treatment. Of course, if coma should come on, he would have recourse to alkaline intravenous injections without loss of time.—*Lancet*, Feb. 9, 1889.

THE LOCAL TREATMENT OF LARYNGEAL PHTHISIS.—DR. A. SOKOLOWSKI, of Warsaw, concludes an article on the treatment of laryngeal phthisis, with the following summary:

1. A cure of laryngeal phthisis, though seldom effected, is possible.

2. Cicatrization of each ulcer which takes place by itself, or through local application, is closely related to the general condition and the character of the local changes in the lungs.

3. The best local results are obtained from the combined treatment by lactic acid, surgical procedures, and the galvano-cautery.

4. General treatment should go hand in hand with the local treatment.—*Wiener klin. Wochenschrift*, No. 4, 1889.

MEDICATED THALLIN BOUGIES IN GONORRHOEA.—DR. JOHN M'CRAW, of Dublin reports the following case: H. J. had impure connection four days before he applied to me for relief. His symptoms were those of acute gonorrhœa, the disease having been considerably aggravated in con-

sequence of his having been drinking heavily both before and since he contracted it. The yellowish-green discharge from the urethra was abundant; he suffered severely during micturition, and there was great tenderness along the whole course of the penile urethra. The night before he came to me he was obliged to rise five times to pass water. He had the disease seven years ago, and was then under treatment for about two months with a medical gentleman in this town, who gave him copaiba. The line of treatment adopted in this case was by the introduction into the urethra of medicated bougies, and the medicament consisted of sulphate of thallin of 5 per cent. strength. Before introducing the bougie I made the patient micturate, in order to clear the urethra of discharge, and I then passed the bougie up to the ring, and directed him to hold the meatus quite close, so that none of the application could flow out as it melted. I kept him lying on his back for 20 minutes, at the end of which time I withdrew the spring and closed the meatus with cotton wool. During the time the bougie was in the urethra he complained of smarting pain, but after I withdrew the spring he said the pain ceased entirely, and he expressed himself as feeling comfortable. He introduced one every evening after this, following carefully the directions I gave him; and on the third day after he had been with me he called to say he was quite cured, having no discharge of any kind, and no pain on passing water. The day following happened to be his busiest day in the week, as he had to work to 12 o'clock at night, and be on his feet the greater part of that time. In consequence of this he could not get to using his bougie that day at all, and on the next morning there was a slight return of the former symptoms; but he began anew his treatment, and after using two more bougies, was again perfectly cured. He has remained so since, although he has undergone the heavy day of the week which caused him to relapse before, and this time with impunity. No bad after-effects of any sort resulted from the treatment, and my patient was very grateful, as well as very much surprised and delighted, for he had been looking forward to a course of copabia-drinking with anything but pleasant recollections.—*Dublin Jour. Med. Science*, March, 1889.

MERCURIAL TREMOR.—M. LETULLE reports the case of a man of 39, who was, at his work, exposed to emanations from the acid nitrate of mercury. For eleven years he suffered in no way except that his teeth became black and fragile. At this time he served three years in the army and then resumed his trade. Ten years later he had his first attack of mercurial tremor. A course of sulphur baths and iodide of potassium relieved but did not cure him. The tremors were worse in the morning, almost imperceptible about 4 to

5 P.M., and again very marked in the evening. Suddenly one day the tremors became so violent that the man was thrown down by them and was so violently convulsed that he could not walk; in this condition he was brought to the hospital.

When perfectly at rest in bed the movements were slight, but they were very much intensified by any voluntary effort. The motions were extensive, rapid, arrhythmic, not like those of any disease, though choreiform, and were, perhaps, more marked upon the left side. There was an anæsthetic area on the back of the right forearm and hand, and the man said that since the first attack of tremor his vision had been impaired. There was some narrowing of the left visual field without any notable color-blindness. These peculiar symptoms led Letulle to name the malady *mercurial hysteria*. He accidentally discovered that constricting the limb would check the tremor, and he finally permanently stopped it by the application of an elastic ligature, and the passage of a magnet up and down the limb. He therefore concluded that mercury in a case like this produced no serious structural lesion in the brain or cord, but appeared to exalt in a singular way the activity of the nervous centres and profoundly disturb the harmony which governs their functional synergy.—*La France Médicale*, November 8 and 10, 1888.

ALPHA-OXYNAPHTHOIC ACID AS AN ANTISEPTIC.—It is now six months since alpha-oxynaphthoic acid was brought out as an antiseptic. Helbig (*Therap. Monatsh.*) records what has been effected by it so far. He recommends a collodium made from it (0.5 per cent.) as a substitute for iodoform collodium, as it is a very strong antiseptic. It has the advantage over the iodoform preparation of not irritating the skin of sensitive subjects, and of being more staple. There can be no doubt that iodoform collodium is by no means a satisfactory preparation. Efforts are being continually made to improve it, so that this substitute should find a wide field for trial. The same author recommends an antiseptic wool in the treatment of ulcers and wounds. He prepares it as described under:

R Acidi α -oxynapth 5j
Spiritus vini rect 5viij
Glycerini 5iss
Fuchsin gr. 1-12
M

The resultant liquid is sufficient for 7 ounces of wool, and gives a product which, when dry, contains about 1.4 per cent. of acid. The paper shows, on the whole, that there is plenty of room for good new antiseptics, although we have so many already.

PHYSIOLOGICAL ACTION OF SULFONAL.—From some experiments on this subject W. J. SMITH

draws the following conclusions: 1. In moderate doses sulfonal is completely transformed into very soluble compounds (sulphacids); in this respect it is distinguished from a large number of similar bodies, the disulphides among others, which pass through the organism unchanged; for example, ethylene diethylsulphide. 2. Sulfonal does not affect the elimination of sulphuric acid, which shows that the organic compounds formed by sulfonal have great stability. 3. In moderate doses sulfonal has no influence on organic combustions.

COMBINATIONS OF LANOLIN.—DR. STERN, a specialist in skin diseases, publishes in the *Therap. Monatsh.* some notes on new combinations of lanolin. "Sapolanolin" is a mixture of 2½ parts of anhydrous lanolin to 2 parts of pure soft soap. With this base all medicaments may be mixed with the exception of salicylic acid. The author used it for applying boric acid, tar, white precipitate, resorcin, etc. These ointments were found to be specially advantageous in inveterate infiltrated eczema, in mycosis and seborrhœa. Against psoriasis capitis he used an ointment made as described hereafter:

R Hydrarg. precip. alb. 5j
Saponis mollis 5iv
Lanolin anhyd. 5jss
M

Anhydrous lanolin is of course simply the ordinary lanolin of commerce, deprived of its 25 per cent. of water. Sapolanolin with white precipitate, is, according to the author, just as effective on the head as chrysarobin is on the body. As a paste which adheres to the skin, without necessitating the use of a bandage he used a mixture of

Oleum olive 5ij
Cera flava 5j
Lanolinum anhyd. ana 5ss

The ointment is a pale yellow color, and of thick consistence. It can be mixed with all other ointments when, for the treatment of eczema, the use of such a paste is indicated. Another suggestion of the author is the use of lanolin injections for the urethra, such as the following:

R Zinc sulphatis gr. x
Aquæ 5ij
Dissolve and add to—
Lanolini anhyd. 5v
Olei amygdal 5iij
M

Or, as under—

R Acidi salicylatis gr. v
Dissolved in—
Olei amygdal 5iij
Lanolini anhyd. 5j
M

Injectations are made with an ordinary syringe, and it is found that the medicaments are very readily absorbed by the mucous membrane.—*Provincial Medical Journal*, March 1, 1889.

PRACTICAL ANATOMY IN THE COLLEGES.

In looking over the "requirements for graduation" of the ninety degree-conferring regular medical colleges of the United States, one is particularly struck with the variety of requirements in regard to practical anatomy. Some of the schools require thorough dissection of the whole body; some "certificates of at least one course of practical anatomy;" others "practical anatomy during two sessions, and dissection of all parts of the cadaver;" still others require "dissection of one lateral half of the body;" and some do not mention practical anatomy in their requirements for graduation.

What must be the surprise of the recent graduate of a college that requires a minimum amount of dissection, to read that John Hunter, Sir Astley Cooper, and other eminent surgeons of the olden time scarcely considered that they were entitled to their breakfasts until they had done some dissection—and this every day during their professional lives! We would not be understood as holding the opinion that dissection is the best exercise for acquiring an appetite in the morning, nor that it is necessary that each surgeon should spend some part of each day in dissecting. But anatomy can be learned best by dissection; and it appears that practical anatomy is far too much neglected in the colleges. In some of the schools it can scarcely be otherwise than that the student is simply introduced to the study of anatomy. Certainly, some of the graduates are not well acquainted with the subject. Anatomy is a sub-

ject for the practical study of which the medical man has but little time or opportunity after he gets into practice. Like chemistry and physiology, it must be learned at the college, or the chances are, it will never be learned.

Is the incentive to the study of practical anatomy in the schools sufficient? We think not. Not being required, in the majority of instances to pass practical examinations in anatomy, the student, in a large number of cases, thinks it quite sufficient if he knows enough of the subject to write on paper the answers to certain questions. He would view the matter in an entirely different light if he had to demonstrate (as a part of his examination) some portion of human anatomy, especially if he had to make the demonstration before others than the teachers in his college. This should be the more important part of the anatomical examination. And it would be well if it were, or could be, the only kind of anatomical examination before State licensing bodies. The anatomical part of the German *Staats-Examen* is of this nature—entirely practical. The candidate is required to demonstrate a "part" or one of the cavities of the body in the presence of at least two members of the examining board. Clearly, the student that has learned his anatomy from a book can have no place in such an examination. And inasmuch as the practitioner must practice on men rather than on books, this is the only proper method of finding whether the student has a working knowledge of anatomy. At the University of Virginia a part of the anatomical examination consists of actual demonstrations on the cadaver of several parts of the body. Whether such examination is required in any other American colleges we do not know.

It may be said, also, that topographical and morbid anatomy are much neglected in American schools; yet no one doubts their great importance. How many students, or medical men, can point out on the living subject the structures that lie beneath a given superficialities? How many recent or old graduates can make a *post-mortem* examination as it should be made? Are not very many students graduated after hearing lectures on pathological anatomy without having had an opportunity of seeing specimens of the morbid affections of which they have heard?

Why should a student be required to listen to "twice told tales" in the anatomy room, without

having what he hears verified by anatomical demonstrations—apart from the actual work in the dissecting room? And does it not appear to be self-evident that a student can learn more from an autopsy, properly conducted, than from half a dozen didactic lectures on the pathology of a given disease?

These are questions that medical teachers, and examining boards, would do well to ask themselves.

HOT-AIR INHALATIONS IN PHTHISIS.

If one is to accept the statements of DR. A. L. STERN at the last meeting of the Section on Practice of the New York Academy of Medicine, the desideratum that has been so long and so fruitlessly sought for, a positive cure for pulmonary tuberculosis, has now been attained. This cure, Dr. Stern claims, is effected by Dr. Weigert's hot-air inhalation-apparatus, which he exhibited, and the use of which he explained. It is simple in construction, consisting of two copper cylinders, one within the other, and the air to be inhaled, which is heated by means of a Bunsen burner to a minimum temperature of 212° , and thus rendered perfectly aseptic, passes up between the two. The inhalation is to be used for four hours each day—two hours at a time—and it can be taken either in a sitting or reclining posture. It is advised, however, that when first commencing the treatment the patient should use the apparatus for thirty minutes only twice a day. The temperature of the air inhaled is gradually increased from 212° to as high a point as the patient can bear without suffering inconvenience; 482° being the highest temperature as yet reached in any case in these inhalations.

As a result of the hot-air inhalation, it is claimed, there is an acceleration of the pulse, while there is diminution in the frequency of the respirations, and inspiration becomes deeper. There is at first an elevation of the body temperature, the rise being from 1° to 2° ; but after about an hour the temperature again subsides. Under the continued use of the inhalations the difficulty of breathing incident to consumption is soon markedly relieved, and there is at first a lessening, and then a total cessation of cough. There is at first an increase, then a decrease, and finally total disappearance of expectoration. All catarrh-

al symptoms disappear, as do the fever and night-sweats. There is a clearing up of the infiltrated portions of the lungs, and cicatrization of cavities, when these exist, is brought about; while the strength, weight and appetite of the patient gradually increase. The microscopic examination of the sputa generally shows at first an increase in the number of the bacilli tuberculosis, but afterwards there is a total disappearance of the bacillus, and a complete cure is effected. The shortest period in which total disappearance of the bacilli has been noted is four months. This method of treatment, Dr. Stern said in conclusion, has now been employed in 150 cases, 50 of which were published in Vienna.

All this reads like a fairy tale, but it can be safely assumed that it will not be long before the method has been given a sufficiently extended trial to enable the profession to decide upon its merits. Dr. Weigert, the inventor of the apparatus, is a graduate of the College of Physicians and Surgeons of New York City, and is now residing in Berlin. We learn that Dr. Trudeau, of Saranac Lake, N. Y., has already used the hot-air inhalations with success in a number of cases. There is but little doubt that this method of treating phthisis will be extensively tried. It is to be hoped that the trials will be as careful as extensive, so that whatever of value there may be in the method will not be vitiated by and wrong conclusions drawn from improper and careless experiments and administrations.

ILLINOIS STATE MEDICAL SOCIETY.

The Thirty-ninth Annual Meeting of this Society will be held in Jacksonville, commencing on Tuesday, May 21, 1889, at 10 o'clock, A. M. Only two months elapse before the time specified, and it is important that all parties intending to attend or contribute to the interest of the meeting, should be actively preparing their work. The several State Medical Societies constitute the chief and proper basis of the National organization of the profession, and they should be cordially sustained by the most learned and active in all departments of medicine and surgery.

There is room in the State Society for the advocates of every legitimate interest to work, and interchange thoughts and facts with each other, thereby actively advancing the practical interests

and promoting the unity and influence of the whole profession. In a country as large as ours there is no method of complete and efficient professional organization, except that which begins with the municipal and county societies, progresses from these to the State, and from the State to the National; thus establishing the channels of universal intercommunication, and the opportunities for personal intercourse and of harmonious action. During the next two months the State Medical Societies of nearly all the States occupying the middle and northern part of the great interior valley of this continent will hold their annual meetings and we hope to see larger assemblages, a greater number of well prepared papers, and the results of more thorough scientific investigation, in all of them, than at any previous time in their history. The annual meeting of the American Medical Association will follow at Newport, R. I., commencing on the 25th of June. For four previous years that great National organization has held its annual meetings in this interior valley, with steadily increasing attendance. As the next meeting is to be held on the northeastern border for the first time since 1865, it is very desirable that all the State Societies of these great interior States should send full delegations to the meeting at Newport, thereby not only cordially reciprocating the favors of the past four years, but firmly cementing the bonds of friendship and materially adding to the scientific and practical interests of all.

THE MICROBES OF THE STOMACH.

This was the subject of a recent communication to the Académie des Sciences, by M. ABELOUS. In the fluid obtained by frequent lavages of his own stomach (empty) he has isolated 16 species of microbes, the morphological characters and action of which on alimentary substances, he has studied. The 16 species comprise 7 known microorganisms: the *sarcina ventriculi*, the *bacillus pyocyaneus*, the *bacterium lactis aërogenes*, the *bacillus subtilis*, *bacillus mycoides*, *bacillus amylobacter*, and the *vibrio rugula*. Of the 9 species that have not been described, 1 was a coccus, and 8 were bacilli. All these microbes resist the action of artificial gastric juice for a time much exceeding the mean duration of stomach digestion, especially when the cultures were rich

in spores. Each of these species of microbes has a more or less energetic action on certain alimentary substances: 10 attack albumen, 12 fibrin, 9 gluten, 10 cause the more or less complete transformation of lactose into lactic acid, and 13 form variable quantities of glucose from starch. But the most remarkable results, says Abelous, are seen in the action of all these microbes, at the same time, on an alimentary substance, especially when some saliva is added to the substance. Very rapid and very energetic decomposition sets in, with the evolution of gas and the formation of such products as leucin, tyrosin, indol, skatol, certain fatty acids and ammoniacal compounds. It is a fair inference that these microbes are very important factors in the process of digestion. The real theatre of their action, says Abelous, should be the intestine, not the stomach, since the duration of stomach digestion is not sufficient to allow the microbes to decompose appreciable quantities of alimentary material—if one may draw conclusions on this point from a study of artificial digestion.

EDITORIAL NOTES.

THE FLORIDA STATE BOARD OF HEALTH is now, so far as the legislative act is concerned, a reality; it is thought that the Governor will soon appoint the members of the Board. We have not seen a copy of the act, and do not know its conditions and provisions. The Board is to consist of three members, who will select from the State at large a secretary and an executive or health officer, the latter to be a physician. Whether the emoluments of the officers will be sufficient to warrant them in giving the proper attention to their duties we do not know. As a general rule such is not the case. Governments cannot expect to have offices properly filled so long as private enterprise is allowed to outbid the public services. Yellow fever cost the State of Florida millions of dollars last summer; it can never recover that money, but by paying efficient men to look after its health it may avoid the loss of millions in the future.

GENERAL PARALYSIS IN THE FEMALE, in relation to certain menstrual troubles, has been investigated by DR. GILBERT PETIT (*Thèse de Paris*, 1888), who concludes, from 59 cases, that the development of general paralysis in women

often causes menstrual troubles. These troubles are characterized sometimes by a sudden and definite arrest of the menstrual function, sometimes by marked irregularity of the menstrual periods. When there occurs a remission in the course of the general paralysis, the regularity of the menstrual function is re-established. The patients that have no menstrual trouble during the diffuse meningo-encephalitis, appear to resist the disease better than those whose menstruation is completely arrested or made irregular.

A MEDICO-LEGAL SOCIETY has been organized in Belgium. At present the only medico-legal laboratory that exists in Belgium is attached to the University of Gand. Dr. Vleminckx, of Brussels, is President of the new Society, and Dr. C. Moreau, of Charleroi, Secretary. The Society begins with a membership of 40 physicians.

A NEW PRIZE IN HYGIENE has been founded by the widow of the late Dr. Pier d'Hony, of Milan, in memory of her husband. The prize amounts to 1000 fr., which the Royal Italian Society of Hygiene will award for the best memoir on a question of industrial hygiene, special attention being paid to prophylaxis and precaution against disease, injuries, and accidents of any particular field or fields of labor. The memoirs must be in the hands of the Society by February 29, 1890.

TOTAL DESTRUCTION OF THE SPINAL CORD in mammals by means of a stream of cold water, which prevents hæmorrhage, has been studied by M. GLEY. This method enables one to observe the different vaso-motor actions, independently of all nervous influence of central origin. When the cord has been destroyed in this way strophanthus causes a marked general vaso-constriction. By this method one may study the origin of the vaso-motor phenomena produced under the influence of certain medicamentous and toxic substances.

THE INFLUENCE OF TOBACCO-SMOKE ON MICROBES was the subject of a note by HAJECK at the meeting of a Vienna Medical Society on January 17. Basing his researches on the experiments of Tassinari, of Pisa, who showed that tobacco-smoke hindered the development of microbes, Hajeck looked up the vital statistics of Vienna, to see whether diphtheria is less prevalent among

men, who generally smoke, than among women. He found that for the past four years the ratio of diphtheria cases in men to those in women was 1:2.8, or almost three times as many cases in women. This, he claims, bears out the experimental results of Tassinari. It may be suggested, however, that men, as a rule, lead more of an open-air life, and do not, so frequently as women, nurse children and others suffering from diphtheria. Israel showed that tobacco-smoke destroys bacteria-cultures. But it seems that Hajeck has based his conclusions on insufficient data. We should know the other habits of the males that had diphtheria, besides knowing whether or not they smoked.

SUBUNGUAL PULSE.—MARIO SACCHI describes in *Riforma Medica*, 1888, No. 224, a second case of subungual venous capillary pulse. The first case was seen by Giocco in a patient that had tricuspid insufficiency. Sacchi's patient was a woman 60 years of age, with relative tricuspid insufficiency, in which a systolic return current into the veins produced the venous capillary pulse.

THE UNIVERSITY OF PENNSYLVANIA is discussing the extension of its medical course from three to four years. At a recent meeting of the Board of Trustees Dr. William Hunt said, according to the *Philadelphia Press*:

As we raise the standard of the University it becomes necessary to lengthen the term of the medical course, and this will unquestionably be done before very long. In fact, it must be done. The University is one of the most prominent institutions in the medical history of the country. Its course at present provides for a compulsory study of three years in order that the student may obtain the degree of Doctor of Medicine, but our catalogue now recommends that students pursue a four years' course. The additional, or what may be called a post-graduate, year of study, is already provided for, and I think that the extra year will very soon be added to the present three years' term.

At the same meeting of the Trustees a new chair of Histology and Embryology was created, and Dr. George A. Piersol elected Professor. Dr. De Forest Willard was elected Professor of Orthopædic Surgery, which is practically another new chair, and Dr. Samuel G. Dixon was elected Pro-

fessor of Hygiene, in connection with which chair a laboratory will be established. It is announced that Mr. Henry C. Lea has given to the University \$25,000 for the use of the laboratory of hygiene, conditioned on the raising of an equal sum by the University. Of this additional \$25,000 a goodly portion has been subscribed or guaranteed, and it is hoped that the remainder will be speedily forthcoming.

ASSOCIATION NEWS.

American Medical Association. Fortieth Annual Meeting.

To be held in Newport, R. I., June 25, 26, 27 and 28, 1889.

The names and addresses of Section Officers and other officers of the Association are printed on advertising page 25.

Special Attention is called to the following Rules of the Association:

It shall be the duty of every member of the Association who proposes to present a paper or report to any one of the Sections, to forward either the paper, or a *title* indicative of its contents, and its *length*, to the Chairman of the Committee of Arrangements at least one month before the annual meeting at which the paper or report is to be read. It shall also be the duty of the Chairman and Secretary of each Section to communicate the same information to the Chairman of the Committee of Arrangements concerning such papers and reports as may come into their possession or knowledge for their respective Sections, the same length of time before the annual meeting. And the Committee of Arrangements shall determine the order of reading or presentation of all such papers, and announce the same in the form of a programme for the use of all members attending the annual meeting. Such programme shall also contain the rules specified in the By-laws and Ordinances concerning the consideration and disposal of all papers in the Sections.

No report or other paper shall be entitled to publication in the volume for the year in which it shall be presented to the Association, unless it be placed in the hands of the Committee of Publication on or before the first day of July. It must also be so prepared as to require no material alteration or addition at the hands of its author.

Every paper or address received by this Association, or by a Section, and ordered to be published, and all reports of Committees, and all plates or other means of illustration, shall be considered the exclusive property of the Association,

and shall be published and sold for the exclusive benefit of the Association.

ORDINANCES.

Resolved, That the several Sections of this Association be requested, in the future, to refer no papers or reports to the Committee of Publication, except such as can be fairly classed under one of the three following heads, namely: 1. Such as may contain and establish *positively* new facts, modes of practice, or principles of real value. 2. Such as may contain the results of well-devised original experimental researches. 3. Such as present so complete a review of the facts on any particular subject as to enable the writer to deduce therefrom legitimate conclusions of importance.

Resolved, That the several Sections be requested, in the future, to refer all such papers as may be presented to them for examination by this Association, that contain matter of more or less value, and yet cannot be fairly ranked under either of the heads mentioned in the foregoing resolution, back to their authors with the recommendation that they be published in such regular medical periodicals as said authors may select, with the privilege of placing at the head of such papers, "Read to the Section of the American Medical Association on the day of 18 . ." (Vide *Transactions*, vol. xvi, p. 40.)

Resolved, That no report or other paper shall be presented to this Association unless it be so prepared that it can be put at once into the hands of the Permanent Secretary, to be transmitted to the Committee of Publication. (Vide *Transactions*, vol xvii, p. 27.)

SOCIETY PROCEEDINGS.

Chicago Medico-Legal Society.

Meeting of March 2, 1889.

THE PRESIDENT, DR. E. J. DOERING,
IN THE CHAIR.

CLARK BELL, ESQ., of New York, read a paper on

ELECTRICITY AND THE DEATH PENALTY.

(See THE JOURNAL of March 9.)

DR. FRANKLIN H. MARTIN said he did not feel competent to add anything to this paper, on the subject of execution by electricity. If, however, our criminals are to be executed at all there seems to be very little doubt in regard to the superiority of electricity over the gallows, especially if we take into consideration this interpretation of the law as given by the Commission appointed by the State Legislature of New York to investigate this subject, that is, that the State does not

claim the right to inflict punishment upon the homicide in a vindictive or retaliatory sense, or as in any degree as punitive or compensatory for the act committed; that is, we have no right, if this Committee interpreted the law correctly, to inflict other punishment than the death penalty upon our criminals. Electricity seems to me to be the force that should be applied, for this reason. In hanging there are two causes of death; one is the destruction of the nerves of organic life by the breaking of the neck and pressure upon the spinal cord, the other is from strangulation. We have both of these effects where the criminal is properly executed. If from the time the noose begins to tighten upon the neck of the criminal until death is declared by the physician in attendance, in any degree measures the time that the criminal must suffer, we certainly can see that electricity is superior. While this cord is tightening on the neck of the criminal and death is taking place, a current of electricity might pass through the criminal and do its work and pass to the sun and return, so that if consciousness ceases at the time the current passes through the criminal's spinal cord and brain much suffering must be prevented. The consideration of methods has been so thoroughly discussed by the paper that there is certainly very little left to say. In the first place the position of the criminal must be considered; and the electrodes that conduct the electricity to him must be properly applied; also the kind of current and its strength must be considered. The electrodes described in the paper, that is, large sponge electrodes, or electrodes 3x4 inches covered with sponge or chamois and saturated with salt water solution, must be the electrodes applied if we desire to prevent mutilation. If these electrodes are applied one at the top of the head and the other at the back of the neck, the part of the human system in which consciousness lies is destroyed immediately. Experiments immediately made on lower animals show that the structure of the brain with a powerful alternating current, is entirely destroyed. This is not the case, of course, with hanging, where strangulation is the cause of death. The current described as alternating, is possibly not thoroughly understood by all. It is not an interrupted current, as one statement in this paper might lead one to believe; it is a current that changes its polarity at every interruption; the current is a to and fro current. In a current from a Westinghouse electric light dynamo the polarity is changed 600 times in a second, and the current is deadly in the extreme. Although it seems almost presumptuous for any one to bring a question up at this time after the opinion expressed by Mr. Edison, still there is a question with regard to the proper apparatus for the execution of criminals. It seems that the dynamo, engine and apparatus necessary for execution by the method described

in this paper can be obtained only at an expense of \$5,000. The kind of electricity that is most deadly, and we have a great many examples of its action, is the current in the lightning stroke; that is, the static electricity, or the Franklinic form of electricity. While it is the same electricity, probably, as that we receive through our dynamos, it is one of very high electro-motive force. A machine with a 54-inch wheel and an apparatus that would cost in the neighborhood of \$500 will give an instantaneous shock that will prove as deadly, without doubt, as the alternating current generated by a \$5,000 apparatus. In adopting electricity as the mode of execution there are certainly grounds yet for further experiments.

DR. PLYM. S. HAYES: There are several points of interest in regard to death by electricity that I have not seen mentioned in recent literature on the subject. Decomposition takes place almost immediately after death by lightning. Prof. Richman, of St. Petersburg, a contemporary with Franklin, had in his laboratory a metallic ball which passed, by means of a metallic conductor, through the ceiling and terminated on the roof in a sharp point. When not using this electricity he connected this ball, by means of a chain, to the earth. When he wished to collect the electricity he would disconnect the chain. One day he passed within 18 inches of this ball and the current jumped across and he was killed, and so rapidly did decomposition set in that he had to be buried almost immediately. Again we find that when death occurs from lightning-stroke *rigor mortis* does not occur. Again we have instances in which the person is fixed immovably, sometimes standing.

In looking up the subject for life insurance I found there were one or two men in the city of Chicago who had taken a current of electricity of sufficient strength, under ordinary circumstances, to kill a man, but who escaped with their lives. Again, I found that if the current was gradually increased and then as gradually diminished, a man could take a tremendous current, one which would usually have killed him, but being a continuous current of great evenness gradually increasing and diminishing, the man escaped without injury. There is a point mentioned in this paper, and which I have seen mentioned in some of the medical journals. One journal stated that 500 volts would kill. And in the paper that has just been read the point has been raised in regard to the number of volts necessary to be used, and it is recommended that from 1,000 to 1,500 volts of current be used. Now they say nothing of the ampèreage of the current. It seems to me that ampèreage cuts just as much of a figure as voltage. In the case of static electricity we find that between the conductors of a machine, where we can get a spark of 6 or 7 inches, we will have an electro-motive force of not less than 3,000 volts, and

yet there is not one of us in this room but can take that through his body without injury, because there is no ampère to speak of. But if the spark jumps a foot then it is decidedly more dangerous; but even then it depends upon the condensers (Leyden jars) connected with the machine. We know that we can take a shock from a machine throwing a spark 7 inches, and yet with the same shock, where more volume (ampère) is given, we know that the result would be fatal. There is an induction coil in England that gives a spark of not less than 24 inches; it is estimated that that would destroy life instantly, and it is a dangerous plaything, to say the least.

To use the frictional machine for the death penalty would not be advisable because, even with the best frictional machines produced at the present time it would be impossible at certain seasons of the year, during the summer especially, for weeks at a time, to get a sufficient current to carry out the penalty. I think when we speak of voltage we should have ampère. In the arc light the ampère is great and we have a voltage comparatively low as compared with the voltage of the static electric machines.

I received at one time a current from 1,140 cells of the gravity (Callaud) battery. It was before the days of electric light in Chicago, except that obtained by the battery, and a gentleman was very anxious to use a lantern he had imported from England, in which the electric current was to be employed; so we worked up in the top story of the Western Union building one evening and had 1,140 of their battery cells connected together. We got an arc light of 3 inches; that is, the carbons of the lamp were separated 3 inches after the light was started, but the light was so faint that you could look at it with the naked eye, and it probably did not give more light than one of the Edison burners here. I accidentally got hold of the two poles. I was shocked two or three times, the muscles contracted very rigidly, and I had some deep burns on my hands for several days, but beyond that no injury was done to me, and I probably received not less than 1,000 volts through my person. If you say a man has taken a thousand volts, you might as well say a man has eaten a mile of sponge cake; well, he could eat a mile of cake if it was cut thin and narrow enough. And so it is with the electric current, there are two dimensions; there is the electromotive force, the power of overcoming resistance; and there is the ampère, the quantity of volume. Or, the voltage is velocity, while ampère is momentum, that is, it is velocity with mass added to it. Now, a cannon ball may have the same velocity as a musket ball, yet a cannon ball will do many more times the damage that a musket ball will do. The difference is not in the velocity but in the momentum. It seems to me one factor has been omitted in this discussion; ampère-

age has not been taken into consideration in connection with the voltage. Of course, in these electric light machines there is a certain amount of ampère, so there will be no difficulty about the criminals being duly executed by the use of any of the instruments that have been suggested in the paper read to-night.

DR. F. C. HOTZ: As physicians we are not interested in killing people, no matter whether it is done in an apparently brutal manner or in a very elegant manner, but we are interested in allaying suffering. Therefore the question that concerns us, is simply whether the criminal suffers during the hanging or during the time that his head is being cut off, or while an electric current is passing through his body, and by which of these methods does he suffer the most. Some of the speakers seem to take it for granted that hanging inflicts a great deal of suffering upon the person. I don't speak from personal experience, but from what I have read in articles written by good observers and gathered from people that had been called back to life after a rope had been strung around their necks, I think this is a wrong impression. What does suffering or pain presuppose? A man can only suffer as long as he is conscious; whenever our consciousness is gone we do not suffer. We all know that when we give a man chloroform we can inflict any amount of injury on his body and he will not feel it; he will not suffer. In putting the rope around the man's neck, as he is executed in this country, and dropping him down so that his weight tightens the rope quickly, often dislocating the neck and acting directly upon the centre of respiration, the arteries supplying the head are so quickly compressed that the arterial supply is cut off. The fact that the pulse is beating in the wrist does not prove that a person during that time is feeling anything. In the half of a second or a second his consciousness is gone and there is no more feeling. In using the guillotine the arterial supply is cut off at once, and if there is anything that will instantly remove consciousness thoroughly and thereby save the criminal any suffering, it is the guillotine, while the electric current, I understand, has to be applied from fifteen to twenty-five seconds. That is taking a long time to kill a man compared with the guillotine or a rope! I think that these recommendations are based upon a wrong foundation; I do not think there is any suffering or any cruelty connected with the act of hanging. The suffering of the criminal is all done before he drops down, physically and mentally. The recommendation that these executions ought to be done privately, without the presence of any one except the jury, etc., and without even the criminal being notified of the exact moment when it is to be done, is all proper and well. But the electric apparatus is no improvement on the present *modus operandi*. It

requires a costly and cumbersome machine which will seldom be used; and probably, when one wishes to use it, will not be in order. I would suggest that if the State of Illinois wants to improve upon the mode of execution, let us go back to the very classical way the old Greeks did this thing: send the criminal a glass of wine fully charged with prussic acid; with the compliments of the sheriff.

DR. N. S. DAVIS, SR.: Mr. President, I only rise to add a word to what has been said about the common impression as to suffering by hanging. I think the most reliable evidence we can get on the subject is from those who have given much attention to it. Taylor, in his "Medical Jurisprudence," and other authors, agree that the consciousness of the individual following the drop is just like a flash of lightning before the eyes, and that is the last consciousness he has; but the idea in the community is that the individual is suffering as long as his muscles are contracted and his body is moving, or until his pulse stops. You may just as well say that an epileptic man is suffering merely because he is in violent convulsions; when the fact is that he has not the slightest consciousness after the first impression reaches his throat until it passes off; although he is in violent contortions, yet it passes away, and when he comes to consciousness he has not the slightest recollection of suffering at all. So a drowning person, if kept beneath the water, would have no consciousness beyond a few seconds, unless he is skilled and refuses to take breath. The mouth and air tubes fill with water the first breath he takes in and the oxygen can no longer oxygenize the blood, and it is but a very few seconds before he is unconscious, though he may still make muscular movements. We all know that a chicken's body hops about for a considerable time after its head is cut or wrung off, but we do not imagine that the chicken is suffering. I make these remarks merely on account of the error that is prevalent about the amount of suffering from hanging. It is said that they make mistakes in adjusting the rope, but want of skill might cause mistakes by any method. Some think that the neck is usually broken, but reliable investigations show that dislocation or breaking of the neck takes place only in a small minority. We know that it takes place in some, but in less than one-quarter. In some the circulation and respiration are cut off and the neck broken, all three, but the majority are rendered totally unconscious and die by simply shutting off the air and stopping the circulation. A man in England took up the trade of exhibiting before popular audiences the practice of hanging, and carried it on for a considerable time by hanging himself, to show the process. He did this successfully and made a profitable business of it for some time, but he finally let himself go a little too far in bringing the pressure

upon the front part of the neck, and actually lost his consciousness completely. The audience supposed it was all play and let him stay there until he was permanently dead. This put an end to that class of exhibitions.

DR. G. C. PAOLI: While I admit that electricity is an improvement on hanging, which is a relic of barbarism, I abhor capital punishments. There is not at present a single nation in the world that can boast of Christianity, with the exception of individuals, but the time is not far distant when capital punishments will be abolished. The question now is, which is the best, the most humane method of destroying life. In my opinion, subcutaneous injections of aconitia. The experiments made on animals during the last twenty years have convinced me that this alkaloid produces death by paralyzing the action of the heart, and consequently the individual dies a painless death in a few minutes.

DR. J. C. HOAG: Although I was puzzled before coming here to appreciate the necessity of any change in the mode of administering the death penalty, I am still more so after having heard this paper read. One point in particular puzzled me very much: The writer says that they make no claim that the State has any right to administer the death penalty in a retaliatory or punitive manner. Now, if there is nothing of retaliation or punishment in capital execution I think we may as well abolish it altogether. To my mind capital execution is executed not so much to rid the State of a dangerous member of society as to deter others from the commission of similar atrocities. Then again, as has been stated, the administration of the death penalty by means of electricity is likely to be both a cumbersome and expensive innovation. The administration of the penalty by means of poisons I think is open to very grave objection; that is, if easy means of poisoning are made known to the public it will certainly have a tendency to increase suicide. The public, becoming familiar to a greater or less extent with these powerful agents, will know what to choose, and they will no longer resort to the uncertain and unpleasant rat poison, but they will at once adopt the poisons approved by the State. Again, I do not know that it is necessary to divest the death penalty of a certain amount of horror. If they that are obliged to administer it are familiar with the fact that the criminal at once loses consciousness, I do not know that it is necessary to relieve the public mind from all apprehension on this subject. I think something might be done in the way of making the death penalty a little less attractive. Of course there is no doubt of the potentiality of electricity to dispatch the criminal *tuto cito et jucunde*, but I do not think it is necessary to execute him *pleasantly* if the means adopted be safe and rapid. With regard to the various modes of execution, I have long thought that there was

nothing better than the guillotine. Hanging is well enough if the rope does not break, but there seems to be very little difficulty in execution by means of the guillotine. Although I have never seen an execution by this means I have examined the guillotine, and always thought that it was a rapid and satisfactory method.

DR. J. E. STUBBS: I wish to place myself on record as being in favor of hanging in preference to execution by electricity. It has been remarked by others that the victim becomes unconscious almost immediately in hanging; and I think it is the experience of those that have fallen from any considerable height that at the moment they lost a firm footing, consciousness almost immediately ceased, and I judge it is the same way in hanging, when the drop falls consciousness ceases, only a sensation of falling is realized, and the sudden jerk ends the physical suffering instantly. The pain is the mental dread of yielding up life. I cannot see that there would be any improvement in death by electricity, for it is not certain whether electricity kills in five seconds or half an hour. Some persons have taken large quantities of electricity and have lived; but I do not know that we have any record of a being legally hanged for half an hour and coming to life again. We have no positive record of man having consciousness after he had reached the end of the rope in the drop from the gallows: Until a better way of executing criminals has been demonstrated I am in favor of hanging.

DR. GEO. E. WEBSTER: With regard to whether the criminal loses consciousness or not until after the heart ceases to beat, it is a well-known fact that in cold blooded animals the heart may continue to beat for several hours after removing it from the body. In warm blooded animals the heart beat is automatic and it will continue to beat a long time after removal. I have succeeded in keeping a mammalian heart beating for a number of hours after removing it from the body. So that the fact that the heart is beating, and that we can feel the pulse, does not indicate life or consciousness. As to the point brought up in regard to drowning: it is a well-known fact, and there is one instance on record of an individual who lived after being submerged for fifteen minutes. During the 15th century there was a law in Germany to punish the crime of infanticide by death, by drowning. The law being that the woman should be placed in a bag with a cock and a cat and drowned, being submerged for fifteen minutes. A case of this kind occurred in which there was spontaneous recovery after the woman had been submerged fifteen minutes.

THE WESTERN NORTH CAROLINA MEDICAL COLLEGE, it is said, is the name of a new medical college to be established in Asheville.

Medical Society of the District of Columbia.

Stated Meeting, November 28, 1888.

SWAN M. BURNETT, M.D., VICE-PRESIDENT,
IN THE CHAIR.

Dr. George Woodruff Johnston presented microscopic slides of a case of *Supposed Primary Cancer of the Fallopian Tubes*.

Dr. J. Taber Johnson presented the specimen and read the history of a case of *Cancer of the Ovary*.

DR. D. S. LAMB presented the specimen and gave the notes of the necroscopy of a case of

CANCER OF THE RIGHT KIDNEY.

Dr. N. S. Lincoln gave the following history of the case: The man first consulted him in the early part of the summer of 1888 for pain in the right side, irritability of the bladder and bloody urine. He sent a specimen of urine to Dr. Schæffer for microscopical examination, and he reported the presence of blood, pus and other elements of malignant disease. There was a tumor, about as large as the fist, on the right side, which descended about half way to the bladder. There was pain in this region which he had had since January, 1888. He diagnosticated malignant disease, and told the man's family that it was necessarily fatal. Dr. J. Ford Thompson was then called in consultation and the patient was examined under chloroform. The tumor was now quite movable, and Dr. Thompson recommended its removal. There was no enlargement of the left kidney noticeable. Dr. Lincoln did not agree to the operation proposed by Dr. Thompson because he believed the tumor to be malignant. Dr. D. Hayes Agnew, of Philadelphia, was then summoned. He agreed with Dr. Lincoln as to the malignancy of the tumor and would not sanction an operation. The man gradually failed and died. The growth was movable when Dr. Thompson examined it, and, consequently, seemed favorable for an operation.

Necroscopy on Horace S. J., white, æt. 61, who died Nov. 3, 1888. Made for Dr. N. S. Lincoln. Old pleuritic adhesions both sides; some hepatization in lower lobes of lungs; several small deposits of obsolete tubercle; some pus in bronchial tubes. Heart small; slight atheroma of aortic valve and aorta. Liver small; showed several cancerous nodules, from very small size to 1.5 inches in diameter; some softened in center. Spleen small. Pancreas normal. Greater omentum contained several cancerous nodules, size of shellbarks, and softened in center. Stomach normal. Duodenum firmly adherent to pelvis of right kidney and contained in its wall several nodules of cancer. Scybala in large intestine. Right kidney about twice natural size, lower half a mass of soft cancer, much of it broken down; debris in recent state was mixed with blood-clot

and contained about ten calculi, large and small, the largest one having branches. Upper half of kidney converted into a sac, with wall of varying thickness; in recent state sac contained purulent urine, and was no doubt formed by pressure of subjacent tumor on ureter. Capsule of kidney was everywhere adherent, and fatty capsule contained several masses, size of shellbarks, softened in center. Pelvis dilated and ulcerated. Upper part of ureter thickened and showed small cancer nodules. Right suprarenal capsule enlarged and cancerous. Left kidney weighed 7 oz.; showed several cancerous nodules, superficial and deep, some of them softened; papillæ swollen, with minute cysts of surface; pelvis dilated from pressure of adjoining tumor of kidney. Bladder and prostate normal. Inferior vena cava dilated and opposite kidney contained blood-clot adherent to wall. Suprarenal vein also contained blood-clot. Abdominal aorta atheromatous. Connective tissue along right side of lumbar vertebræ thickened and firm. Some small exostoses on bodies of corresponding vertebræ.

DR. E. M. SCHLEFFER read a paper on

THE MICROSCOPICAL DIAGNOSIS OF CANCER.

(See page 403.)

DR. J. FORD THOMPSON took special interest in this subject of diagnosing cancer by the microscope, as well as in the case presented to-night. He could not agree with Dr. Lincoln in refusing to sanction the operation, because the diagnosis of malignancy had been given. A large percentage of tumor removed are malignant; two have been reported to-night of which one is well and the other is rapidly recovering. Dr. Lincoln's case looked favorable for a nephrectomy as the tumor was movable. The uterus or breast is removed for cancer if the surrounding tissues are not too much involved. Hysterectomy for cancer is comparatively favorable; he had operated on a case two years ago, and the woman is now doing well. If the complications had been found or known to have existed he too would have opposed an operation; but these were only found at the autopsy. He could not agree with Dr. Lincoln in excluding all cases of nephrectomy because of malignant disease. He had never seen a case in which he would rely upon the microscope for the detection of malignant cells in any fluid of the body. He was not alone in this opinion as most surgeons consider that an absolute diagnosis is impossible. In malignant diseases of the bladder surgeons do not rely upon urinary analysis. It is impossible to make a correct diagnosis from decayed cells found in the fluids of the body. The same is true of the stomach and intestines when the fluids and cells are discharged. He had accepted such a diagnosis once and that was not right. The recent European experience should teach us that it is

impossible to diagnose with certainty a cancerous growth even when it can be seen and felt by distinguished surgeons and pathologists.

DR. LINCOLN had not based his opinion of malignancy on the cancer cells as much as on the patient's general condition, with the tumor and cachexia. From the mobility of the growth he was inclined to agree with Dr. Thompson, but he was compelled to accept Dr. Schæffer's report. The urine may not present cancer cells at all times.

The discussion was continued until the next meeting.

FOREIGN CORRESPONDENCE.

LETTER FROM LONDON.

(FROM OUR REGULAR CORRESPONDENT.)

The Hospital-Ship Queen Victoria—Lady Students of the St. John's Ambulance Association—Sulfonal—Home for Trained Nurses in Egypt—Iodoform and Tar—Administration of Nitrous Oxide and Ether—Tying the Lingual Artery in Excision of the Tongue.

The hospital-ship *Queen Victoria* which has been built at Great Yarmouth as a memorial of the Jubilee, is to cruise in the North Sea, for the purpose of rendering medical and surgical assistance to the fishermen who are engaged in those waters. The vessel was taken into Osborne Bay, where the *Queen* and the *Empress Frederick* drove down through the grounds to the beach and viewed the vessel, after which they witnessed a number of experiments with a new ambulance stretcher. The *Empress Frederick* and her daughters afterwards went on board the ship and were shown all over her, and the *Empress* kindly promised to send a number of books for the library. Last year three vessels which had been sent to the North Sea had 153 in-patients and 7,350 out-patients. The surgery and hospital of the new vessel is fitted up with every convenience likely to be required.

The lady students of the St. John Ambulance Association, in Birkenhead, outnumber the gentlemen, it appears, in the proportion of 153 to 144. An excellent account is given by the examiner of the pupils who, according to his report, were found to be extremely well up in practical work, and all showed great interest in bandaging, removal of injured on stretchers and arrest of bleeding. In addition to practical work, the ladies were given many questions in physiology, etc., and the answers were readily and correctly given. Lest any one should suppose that the ambulance classes are a mere whim and pastime it may be noted that during the last six months of last year the certificated members in Birken-

head were reported to the Secretary to have attended personally to the following casualties: Broken thigh, 3 cases; broken upper or lower arm, 5 cases; broken leg, 4; running over, 3; concussion of brain, 2; apoplexy, 2; pistol shot, severance of palmar arch, and man crushed between carriage step and platform of railway. These are in addition to what are called "police cases," which have a special report book of their own. The Association has now lived long enough to silence all scepticism regarding the substantial benefits of its noble labors.

Sulfonal still continues to attract considerable attention and its use is becoming general. A number of cases of the most varied affections have been treated with sulfonal where there has been nervous insomnia. In 65 per cent. of these sleep was produced within three hours. In the nervous cases this action was even more pronounced, for in 90 per cent. of them the indications were successfully fulfilled. Sulfonal is consequently recommended as a good hypnotic, especially in doses of 15 to 30 grains. Where the insomnia is the result of some direct organic disturbance its action is more or less uncertain. It has the advantage of having no smell and no taste, and it does not affect either the patient's temperature, pulse or respiration, and is consequently to be preferred to chloral or morphine, however, in all cases where there is any heart weakness it is to be guarded against. In other respects the insignificant disturbances which it occasionally produces are not of sufficient importance to be counter indications for its use. Some observers believe sulfonal to be preferred to all other hypnotics. It must be given, as a rule, one hour, at least, before it is desired that sleep should be produced. It has been found quite unreliable when cough or neuralgia are the cause of the insomnia.

Sir Sydney and Lady Waterlow have left London for Egypt. Sir Sydney is proceeding to Cairo for the purpose of permanently establishing the "Home for Trained British Nurses," for which he, in January, 1888, obtained the permission of His Highness, the Khedive. Some nurses have already commenced work in Cairo, and a committee has been formed for the proper management of the institution there. The committee consists of Dr. Greene Pasha, Dr. Milton, with Dr. Sandwith as honorary Secretary.

Experiments have been made with iodoform combined with tar, the notion being that the latter, an oily substance, would diminish the volatility of the iodoform, which is looked upon as the cause of the diffuse erythema caused by the latter, and also because tar often brings gangrenous and septic ulcers into a healthy condition. In the preparation used the particles of tar and iodoform are so intimately mixed together that only hyaline plates can be discovered when the new preparation

is examined under the microscope. The characteristic crystals of the iodoform cannot be discovered at all. The preparation can be very easily pulverized and has a peculiar spicy odor, not at all disagreeable, besides which this odor is so weak that it is only perceptible when the nose is applied to large quantities of the compound in question. If, however, it is required to disguise the slight scent alluded to, it may be done by adding a small quantity of styrax liquidus to the powder and rubbing both substances together. The disease to which the new preparation of iodoform has been applied are soft ulcers, as a dressing after the opening or excision of suppurating or strumous inguinal buboes, gummatous ulcers, and ulcerations of the foot. It is applied thus: The preparation is brushed over the part, which is then covered with a thin layer of wadding, over which an ordinary dressing is applied. The dressing is changed every twenty-four or forty-eight hours. In special cases it has been changed twice a day, for instance, in soft ulcers where the suppuration is very profuse.

Under the title of "Select Methods in the Administration of Nitrous Oxide and Ether," Dr. Frederic Hewitt, of the London Hospital, has supplied a condensed manual for practitioners and students. After some suitable introductory remarks, precise directions are given for the administration of nitrous oxide, for the administration of ether and of nitrous oxide with a small quantity of ether, as well as for the administration of nitrous oxide as a preliminary to etherization.

Dr. F. B. Jerrett, in a paper describing his method of tying the lingual artery in excision of the tongue, especially refers to cases of excision of the tongue with scissors, where the hæmorrhage was often very severe, and even alarming. Moreover, his method, to a great extent, prevents blood finding its way into the air passages, with the subsequent danger of septic pneumonia. Again, in removing the tongue with the scissors, if the artery was not seized directly it was divided, it often retreated, and the bleeding point was with difficulty seen and secured. He had had opportunities of putting the method into practice and had found it effectual. The operation was performed by drawing the tongue well out of the mouth, the frænum and mucous membrane of the floor of the mouth around the half or whole of the tongue if the entire organ was to be removed, was divided in the ordinary way, with scissors slightly curved upon the flat. The tongue next being drawn well forward and upwards, a few fibres of the genio-hyo-glossus muscles were divided and torn deeply through with the fingers. An ordinary aneurism needle threaded with No. 4 Chinese silk was thrust deeply down between the two genio-hyo-glossus muscles, the point being directed downwards and backwards, until it was opposite the second molar tooth. The

point was then turned outward and brought out of the incision previously made through the mucous membrane, unthreaded and withdrawn. The ligature was next tied firmly and as deeply as possible. A pair of clamp forceps were passed down and made to catch the tissues on the distal side of the ligature, to prevent the possibility of the ligature being snipped as the tongue was being removed. If necessary, the same was done on the opposite side.

LETTER FROM PARIS.

(FROM OUR OWN CORRESPONDENT.)

THE PARIS SCHOOL OF MEDICINE—I.

I propose describing as briefly as possible the Paris School of Medicine and the subjects that are taught in it. Those who have not visited this city for the last 15 or 20 years, will scarcely recognize the quarter in which the building of the School of Medicine stands, as the place has become completely transformed. The old building has been considerably enlarged, and fitted up with laboratories for carrying on various researches. The old Hospital des Cliniques which stood opposite has been razed to the ground and the Ecole Pratique has been built on its site. It contains eight pavilions for students carrying on dissection. Each pavilion consists of sixteen tables, and each table supplies room and furnishes material gratuitously to five students.

The degree of Doctor of Medicine in the University of France is conferred by the Faculties of Paris, Montpellier, Nancy, Bordeaux, Lille, and Lyons, under regulations laid down by the Government. The first three are Schools of Medicine, the others are mixed Faculties of Medicine and Pharmacy. There are three Ecoles de plein exercice, Nantes, Marseilles, and Toulouse. There are preparatory schools at Algiers, Amies, Angers, Besançon, Caen, Clermont-Ferrand, Dijon, Grenoble, Limoges, Poitiers, Reims, Rennes, Rouen, and Tours. The studies necessary for obtaining the degree of M.D. extend practically to about five years. During the first three years the student may attend either one of the Faculties, or an Ecole de plein exercice, or one of the Preparatory Schools of Medicine and Pharmacy. The studies of the fourth year can only be pursued in a Faculty or in an Ecole de plein exercice. Before he begins his curriculum the student must take out sixteen inscriptions, but before doing so he must present the diplomas of Bachelor of Letters and of Sciences. Foreign students, however, are admitted to what is called an equivalence of grade in respect to these preliminary studies, that is, certificates of analogous private studies and of examination of arts elsewhere. The following is the course of study through which the student has to pass: First year: physics, chemistry and nat-

ural history. Second and third years: anatomy and physiology. Fourth year: operative surgery and pathology. Attendance on hospital practice, which is also obligatory, commences after the eighth inscription and continues through the remaining period of study. There are five examinations, the first after the fourth inscription and before the fifth. The subjects of the five examinations are as follows: First examination: physics, chemistry, and natural history, in their application to medicine. Second examination: first part, dissections, anatomy and histology (oral); second part, physiology (oral). Third examination: first part, performance of operations, external pathology, midwifery, and operative surgery (oral); second part, internal pathology, or medicine, and general pathology. Fourth examination: hygiene, forensic medicine, therapeutics, materia medica, and pharmacology. Fifth examination: first part, clinical surgery and obstetrics; second part, clinical medicine and practical demonstrations in pathological anatomy. After the five examinations, the candidate must present a thesis on a subject chosen by himself. This he may pass at any time after having pursued the fifth examination, and must be printed at his own expense. But to entitle him to his diploma he must present a certificate of having passed a curriculum in the hospitals and of having attended them regularly for two years. Candidates for the diploma of Officier de Santé (an inferior grade), must also take out sixteen inscriptions, the regulations regarding which are the same as for the degree of doctor. There are six examinations for this grade. First, in physics, chemistry, natural history, and elementary anatomy (bones and ligaments). Second, in descriptive anatomy and physiology. Third, in medicine and surgery. After the sixteenth inscription, which takes place at the end of the third year, there are three final examinations (examens définitifs). First, in dissection, anatomy, and physiology. Second, in operative surgery, medicine, surgery, therapeutics, and materia medica. Third, in clinical medicine, surgery, and midwifery. No thesis is required. Foreign medical practitioners desirous of permission to practice in France as Officiers de Santé, must present their diplomas to the Secretary of the Faculty of Medicine. If the Council of the Faculty report favorably the permission is granted. Foreign practitioners wishing to obtain the degree of Doctor of Medicine must pass the last two examinations and present a thesis, paying full fees for all the examinations they would have had to pass had they gone through the ordinary course. Exception may be made in the case of medical men of acknowledged eminence, to whom the Faculty may at once grant all the privileges of the doctorate. Foreigners may be admitted to any of the French Faculties on presenting their certificates of study in their own countries and paying

an entrance fee of £4. The total cost of fees for the whole curriculum of medical study, and for the whole series of examinations and the diploma of M.D. of the University (during five years) amounts to 1,360 francs. Officiers de Santé pay 450 francs for their examinations.

The School of Medicine in Paris is open to all who wish to attend the courses and take the degrees. Great facilities are afforded to foreign students for the prosecution of their studies, all lectures being given gratuitously, and no payment being required for hospital attendance. For dissections, however, a payment of 40 francs is expected from each student. The instruction in the Faculty is given by the following Professors: Drs. Farabœuf, Anatomy; Mathias Duval, Histology; A. Gautier, Medical Chemistry; Baillon, Natural History; Gariel, Medical Physics; Regnault, Pharmacology; Dieulafoy, Internal Pathology, or Medicine; Duplay, Practical Surgery; Lannelongue, Surgery; Hayem, Materia Medica and Therapeutics; Cornil, Pathological Anatomy; Laboulbène, History of Medicine and Surgery; Tarnier, Midwifery; Proust, Hygiene; Brouardel, Forensic Medicine; Strauss, Comparative and Experimental Pathology; Germain Sée, Potain, Jaccoud, and Peter, Clinical Medicine; Richet, Verneuil, Trelat, and LeFort, Clinical Surgery; Budin (pro tem.), Clinical Midwifery; Grancher, Diseases of Children; Charcot, Diseases of the Nervous System; Panas, Clinical Ophthalmology; Ball, Mental Pathology; Fournier, Diseases of the Skin and Venereal Diseases.

Auxiliary courses are given by Agrégés, or Sub-Professors, on all the above named subjects. Practical instruction is also given under the guidance of Agrégés who are styled Chefs de Travaux and Chefs de Laboratories. The Faculty of Medicine possesses laboratories for the various branches of medical science, and there are also laboratories for practical instruction at several of the hospitals.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

Simple, Non-tubercular, Non-metastatic Abscess of the Lungs—Pigmentation of the Body by Arsenic.

At the last meeting of the Section on Practice of the New York Academy of Medicine, Dr. S. Seabury Jones read a paper on *Simple, Non-tubercular, Non-metastatic Abscess of the Lungs*. This was a subject, he said, which had received but little attention. The affection, however, was comparatively rare, and Trousseau in the first twenty-five years of his hospital practice did not meet with a

single case, though he afterwards reported two cases. Laennec met with only five cases in several hundred autopsies on those who had died of pneumonia. In 1848 Robert Graves reported six cases. When Dr. Jones encountered his first case, now nine years ago, he was unable to find any reference to the subject whatever in any of the text-books to which he had access. Later some attention was given to it in Pepper's System of Medicine; but in von Ziemssen it is referred to only as a sequel of croupous pneumonia. Simple abscess, he thought, would doubtless occur more frequently than it does were it not, as Stokes has pointed out, that the lungs are provided with such an admirable natural system of drainage through the bronchial tubes.

Practically speaking, it is liable to be met with in one of four forms. The first is that in which the symptoms are very obscure from the beginning, and remain so until there suddenly occurs a discharge of purulent matter. In the second form the symptoms resemble those of pleurisy with effusion, and in the third those of pulmonary tuberculosis. The fourth is that associated with the variety of pneumonia which advances slowly from one lobule to another, or is characterized by a tendency to skip from one lung to the other. Dr. Jones said he had personally met with all the forms except the first, but undoubted cases of this variety, occurring in the experience of others, were on record. Abscess of the lungs is always accompanied with a depreciation of the general health, and alcoholism is apparently a prominent factor in its production. It is an affection confined to no particular age, and Dr. L. Emmett Holt, of New York, has reported in the *Medical Record* a case that occurred in an infant only 3 months old.

Dr. Jones' first case was in a young man 17 years of age, of rather delicate health, and affected with lateral curvature of the spine, who came under observation September 25, 1879. While in his usual health he was attacked with severe pain in the left side, accompanied with cough, but no expectoration. At the time he was seen the pulse was 120, and the temperature 102°. Anteriorly there were no abnormal physical signs, but posteriorly, in the subscapular region on the left side, there was complete dullness on percussion, although no râles whatever could be found, and there was still no expectoration. About October 1 a large abscess of the tonsil developed, from which pus discharged freely, and subsequently there was a discharge of purulent matter from the lungs through the mouth. After this the patient made a rapid recovery, and had no further trouble subsequently. He was led to consider this as a case of simple abscess of the lungs, *first*, on account of the short time intervening between the appearance of the first symptoms and the discharge of pus; *secondly*, on account of the occurrence of the tonsillar abscess, showing a tendency

to the formation of abscesses in the system; *thirdly*, from the rapidity of the recovery; and, *fourthly*, because of the dulness found on physical exploration being exclusively posterior.

He was afterwards confirmed in his opinion in regard to the nature of the case by the report of a case published in the *Lancet* by Dr. Henry Payne in 1882. The patient, a man 23 years of age, was treated for some time, but without relief, for pleuritic effusion, and was afterwards supposed, from the nature of the symptoms, to have empyema. Accordingly, an incision was made just above and parallel to the seventh rib in the anterior axillary line. Upon opening the pleura there was a very profuse hæmorrhage of dark venous blood, which could be arrested only by the injection of perchloride of iron solution. About 15 ozs. of pus escaped, and a drainage tube was inserted. There was a very profuse discharge, which in a few days became fetid. The patient continued to do fairly well for nearly a week, when the temperature suddenly rose to 104° and he was seized with violent pains in the chest, and within twenty-four hours after this he died. The autopsy showed the whole of both surfaces of the left pleura adherent, without a drop of fluid in the sac. The external opening made in the chest wall led into a large, irregular cavity situated in the centre of the lung, which was in a state of hepatization. It was therefore seen to be a case of pneumonia, terminating in the formation of an abscess.

Dr. Jones' second case was observed in 1886. The patient was a male, 40 years of age, who was attacked, like the first, with tonsillitis with the formation of an abscess. The suppuration was accompanied with fever, which was ushered in by a chill, and a considerable discharge of pus followed the opening of the abscess. Subsequently he had another severe rigor, followed by high temperature, and coughed up a cupful of pus and dark-colored blood. Still later there was another discharge of similar character, and the matter coughed up was found on microscopic examination to contain the pneumococcus of Friedländer. In this case there was an area of dulness at the base of the right lung, with local tenderness on pressure.

The third case was one in which the symptoms resembled those of tuberculosis. The patient was first troubled with palpitation of the heart, which he believed to be due to gastric derangement. There was a considerable loss of flesh (amounting to 40 lbs.), and the temperature ranged from 100° to 102° , while physical examination revealed an area of dulness in the right subclavicular region. A general tonic treatment was prescribed, and the patient was sent to the country for the summer. In July he coughed up a considerable quantity of pus and dark-colored blood. Afterward the expectoration was profuse, and he suffered from night-sweats and became greatly emaci-

ated. He then began to improve and, as repeated examinations of the sputa failed to detect at any time the presence of the bacillus tuberculosis, the case was regarded as one of simple abscess of the lungs, and a favorable prognosis made. In a few weeks the patient regained his usual health and weight, although a small cavity still remained in the lung. Two years afterward he was seen, in excellent health, and no sign of a cavity could be detected.

He next cited a case reported in the *Lancet* by Mr. T. Pridgin Teale, in 1884. The patient was a male, 54 years of age, who had been ill for three months, and the earlier history of the case was very obscure. Later it was believed that there was fluid in the right pleural cavity, and, after consultation, the thorax was punctured low down with the small trocar of Bartlett's applicator, but only 2 drachms of fluid, which was clear and straw-colored, could be obtained with the suction of the aspirator. Being still confident that fluid was present, Mr. Teale made a fresh puncture higher up, when very offensive, thin, greenish pus appeared; and after careful and continuous aspiration about a pint of pus was withdrawn. A fortnight afterward, the patient in the meanwhile having become more hectic and grown generally worse, an incision was made at the site of puncture, and the pleura opened. No pus appeared (only a small quantity of serum), and the lung felt dense and boggy, instead of crepitant and elastic. On introducing the trocar and puncturing the lung, pus appeared. The puncture was then enlarged so as to admit the finger, and 2 pints of exceedingly fetid pus escaped, after which a drainage tube was inserted, and the cavity syringed out with a weak solution of carbolic acid. The after-progress of the case was extremely critical and tedious, but the patient finally made a good recovery.

Simple abscess of the lungs, although, as had been stated, comparatively rare, Dr. Jones believed to be more frequent than was generally supposed; and in the future he thought it would be more easy to recognize than formerly, since Koch's brilliant discovery of the bacillus tuberculosis now enabled us to make a differential diagnosis. The main point when an abscess had manifested itself was to decide between tubercular and simple abscess, and while great rapidity in the development of the symptoms was always a point in favor of simple abscess, the real test was to be found in the microscope. Including the three cases narrated in the present paper, and exclusive of Graves' six cases, all of which recovered, there were now on record thirty well authenticated cases; and of these sixteen had been operated on, and fourteen had not. If in any case an operation was decided upon, free incision was no doubt the best procedure. He would only operate, however, when the indications for surgical interference were clear.

The chairman, Dr. Page, in some remarks on the paper, referred to pulmonary abscess resulting from the presence of foreign bodies, and said that he had seen a case in which an abscess developed on account of the presence of a bullet which had entered the lung tissue twenty years before; the patient having been wounded in one of the battles during the late war. He was thought to have a cavity, and was troubled with cough and hæmorrhage. The case resulted fatally, and at the autopsy an abscess with the bullet in it was found. Reynolds related a similar case in an old Waterloo soldier, where the bullet remained in the lung forty years before the abscess developed.

Dr. Alfred L. Loomis said that the paper, with its three original cases, and its records of other cases, constituted a valuable contribution to the somewhat meagre literature of this subject. In his own experience simple abscess of the lung was very rare. He had, however, seen a very few cases which were regarded, and very properly, he thought, of this nature, and in one or two instances the diagnosis was proved by post-mortem examination. In all cases of abscess, so far as his knowledge went, the condition had been preceded by the signs of inflammation, more or less active; and he believed that such abscesses formed in lungs which had been previously the seat of fibrinous pneumonia followed by an increase of connective tissue. When subjected to a not very active chronic inflammation abscesses were liable to form in this tissue. Such abscesses he had also never met with except in alcoholic subjects. It was, in his opinion, very difficult to draw the line between circumscribed empyema in certain positions and abscess of the lung, and especially if such empyema broke into the bronchial tubes, so as to allow of the escape of pus. In any case of his own he should be very loath to pass a knife into the lung tissue, and he fancied that the necessity for such a procedure was very rare. As a rule, it diminished the chances of the patient's recovery, and it was better to leave the abscess to open spontaneously.

Before the Section adjourned Dr. Leszynsky exhibited a little girl 9 or 10 years of age in whom the internal use of arsenic, in the form of Fowler's solution, given for the relief of chorea, had produced very marked pigmentation over the entire surface of the body. There was no reason to suspect the presence of Addison's disease, he said, and the case seemed to him a most remarkable one. As to the prognosis, as regards the permanency of the pigmentation, he was unable to express any opinion. If the weak sisters who are now addicted to the use of the "arsenic wafers" so widely advertised for the complexion could once have the opportunity of inspecting this unfortunate patient, it is safe to say that all demand for such preparations in the community would instantaneously cease.

P. B. P.

Neglect of Clinical Teaching.

Dear Sir:—Allow me to make one remark on the question of bed-side teaching, with which you dealt so fully and so well in your editorial of the 9th inst. The difficulty lies entirely in the short three-session course. The students, teachers and patients are here, and there is no reason whatever why Philadelphia, New York, Boston, Baltimore, Chicago, St. Louis and Cincinnati should not have clinical teaching just as thorough, and just as systematic as is given to-day in Edinburgh, or on this continent, in Montreal. Large classes, in large cities with ample hospital facilities, can be perfectly well managed. The lack of a fourth year is the only obstacle. Yours truly,

WM. OSLER, M.D.

1502 Walnut St., Philadelphia. Pa.

BOOK REVIEWS.

DICTIONARY OF VOLAPÜK: Volapük-English; English-Volapük. By M. W. Wood, M.D., Captain and Assistant-Surgeon, United States Army, 8vo, pp. vi, 398. New York: Charles E. Sprague. London: Trübner & Co. 1889.

Volapük, it is said has obtained practical recognition among the speakers of twenty-one different tongues; the speakers of this new language are now numbered by hundreds of thousands, and some "natural" languages can claim no more. It seems not unlikely that Volapük will continue to grow in use for a few years; whether it will after a few years, be more, or less used, it is difficult to say. This may be said, however: no living language appears to present so many advantages for universal use, at present, as Volapük. The *plekels Volapüka*—devotees of Volapük, have been accused of wishing to have Volapük supersede living languages; such is not the case, however. The language is intended as a means of ready communication between persons not conversant with the mother-tongues of one another.

What figure will Volapük cut in the medical literature of the next few years? Some medical articles have been written in this language. At present, however, the medical terms are very few. Possibly in the near future some *sanelik Volapükan*—medical volapükist—will think out substitutes for such terms as hysterrrhaphy, staphylococcus pyogenes aureus, gastro-duodenitis, etc., and we are sure that our German confrères will hail with delight short substitutes for *Bauchspeicheldrüsenschwindsucht* and *Bauchspeicheldrüsenszwölffingerdarpulsader*, not to mention other words of similar length. In fact, the more simple Volapük term might, we suppose, be adopted for general use in the living language. There ap-

pear to be no special difficulties in learning to read Volapük, nor in acquiring the ability to speak it.

Professor Henry Cohn, Director of the Chicago School of Languages, informs us that this is the most complete and the most conveniently arranged dictionary of Volapük published in any language.

TEXT-BOOK OF MEDICAL JURISPRUDENCE AND TOXICOLOGY. By JOHN J. REESE, M.D., Professor of Medical Jurisprudence and Toxicology in the University of Pennsylvania, etc. Second Edition. Revised and Enlarged. Philadelphia: P. Blakiston, Son & Co. 1889.

The first edition of this valuable and convenient work has become well-known to the profession, and consequently needs no extended notice. In this second edition the author has added valuable matter regarding Blood Stains, Suffocation, Ptomaines and Malpractice, and revised the text generally. It is well adapted as a text-book for students of both law and medicine.

TRANSACTIONS OF THE THIRTY-EIGHTH ANNUAL MEETING OF THE ILLINOIS STATE MEDICAL SOCIETY, held in Rock Island, May 15, 16, and 17, 1888. 8vo, pp. xii, 220. Chicago: Jameson & Morse Company.

We must first apologize to the Illinois State Medical Society for having allowed its volume of Transactions to be so long unnoticed in *THE JOURNAL*; the volume appeared in September.

A large portion of this volume is devoted to the reports of committees on the progress made in the various departments and branches of medicine during the year. May it not be said that the day, when such reports are useful or in any way necessary, is past? The custom of having these reports was inaugurated in the Illinois State Medical Society 38 years ago. "Then," as Dr. A. Reeves Jackson remarks in his report on gynecology, "a doctor could wait for his quarterly installment of literary food without feeling any lack of nutrition. . . . Then came the monthly. . . . But now the quarterlies are changing to monthlies, the monthlies to weeklies, and every physician is a subscriber. . . . So that these yearly reports, which may at the first have been a welcomed offering to those who had not always the opportunity of obtaining otherwise the facts which they might contain, have come to be less and less useful."

The volume closes with a volunteer paper by Dr. E. Fletcher Ingals on "Chronic Rheumatic Laryngitis or Chronic Rheumatic Sore Throat," which has been published elsewhere; one by Dr. J. W. Cowden, of Rock Island, on "The External Application of Sulphur in Sciatic Neuralgia," which has been published in *THE*

JOURNAL (Vol. xi, p. 13), and one by Dr. David Prince, of Jacksonville, on "The Possibilities of Volapük for a Universal Language in Relation to Medical Science."

THE YEAR-BOOK OF TREATMENT FOR 1889. Being a Critical Review of the Practice of Medicine and Surgery during 1888. 8vo, pp. viii, 344. Philadelphia: Lea Brothers & Co. Chicago: A. C. McClurg & Co.

In this book is furnished not only an account of the more important advances made in the treatment of disease, but also a review of these advances by competent authorities. The contributions include abstracts and excerpts from the medical literature of all countries for the year ending September 30, 1888. The list of editors includes some of the best-known men in the profession in England. The volume is very conveniently arranged, and the contents make it a most admirable book for any physician.

DEPARTMENT OF AGRICULTURE. Report of 1887. Swine-plague and Cholera critically considered. By FRANK S. BILLINGS, Director of the Patho-Biological Laboratory of the State University of Nebraska. Pamphlet, pp. 64. Lincoln, Neb. State Journal Company. 1889.

This is a "review" of Mr. D. E. Salmon's report on Swine-plague and Cholera, made to the Department of Agriculture in 1887. Dr. Billings says in his preface: "The absolute necessity of forcing this dispute to a final issue must be my excuse for this contribution." What the dispute is, we have failed to discover from the 64 pages of the pamphlet. It is absolutely painful to read anything written with so little dignity of style as this pamphlet, especially when it emanates from a member of the medical profession occupying a public position. The pamphlet is not argumentative; it is abusive, rhetorically involved, and unclear in diction and style. The author claims in his preface to be the devoted servant of his profession, the live stock interests of his country, and his race in all countries. With these masters to serve we think he could spend his time to better advantage than in writing pamphlets of this nature.

MISCELLANY.

MICHIGAN STATE MEDICAL SOCIETY, *Twenty-fourth Annual Meeting*, to be held at Kalamazoo, Michigan, May 9th and 10th, 1889. Much satisfaction is felt in announcing that the membership of the Society is rapidly growing, that added interest in its work is displayed from year to year, and that the regular attendance upon its meetings is constantly increasing. Its members, actuated

by a truly scientific spirit, are working together harmoniously to further the welfare of the Society. The division into Sections for the reading and discussion of papers has greatly facilitated its work. Ours is the first State Society to adopt this plan. Stenographers have been furnished each Section, and verbatim reports of discussions taken. The recent volumes of *Transactions* tell of the gratifying amount of work accomplished. A similar arrangement will be carried out at the next meeting. Mornings will be devoted to the general business meetings of the Society, afternoons to work in the Sections. In addition to the Annual Address of the President, others are promised from the Orators of Sections, as follows:

Upon Practice of Medicine.—Henry F. Lyster, M.D., Detroit. Subject: "The Influence of Mind in the Cure of Disease."

Upon Surgery.—Herman Keifer, M.D., Detroit. Subject: "Surgery within the last Fifty Years."

Upon Obstetrics and Gynecology.—E. W. Jenks, M.D., Detroit. Subject: "The Education of Girls from a Medical Standpoint."

Committees of the different Sections urgently desire that members further the work of the Society by contributing brief papers. Those presented must be fully completed, that the publication of the *Transactions* may not be retarded. Complete abstracts and titles should reach the Secretaries of the Sections not later than April 20th, to insure notice in the official programme.

Railroad certificates for reduced fare will be sent to all physicians, other than members, who desire them, on application to the Secretary.

The Headquarters of the Society will be at the Burdick House, Kalamazoo. All sessions of the Society will be held in the 1st Presbyterian Church, corner of Rose and South streets.

The officers of the Society earnestly solicit the coöperation of all members, to the end that the next meeting at Kalamazoo may prove the largest and most successful in the history of the Society.

Secretaries of Sections.—Practice of Medicine: H. B. Hemenway, M.D., 524 South Park St., Kalamazoo. Surgery: F. W. Mann, M.D., 250 West Fort St., Detroit. Obstetrics and Gynecology: C. Henri Leonard, M.D., 18 John R. St., Detroit.

To be elected to membership necessitates being present.

S. S. FRENCH, M.D., President,
Battle Creek.

GEO. DUFFIELD, M.D., Secretary,
25 Washington Ave., Detroit.

DR. PASCHAL MAXFIELD, the oldest physician in Vergennes, Vermont, died recently, aged 76. He was highly esteemed for his generous character, and held many important offices in the gift of the town and State. He was a graduate of Castleton Medical College.

AN AMERICAN HOSPITAL is one of the features of the City of Mexico. All English-speaking persons that apply are admitted. Regular contributors to the Hospital, who subscribe not less than \$1 monthly, and Americans without means of support, are entitled to attendance and medical treatment in the general ward, free of all charge. Other persons may enjoy the privileges of the Hospital on equitable terms, and private rooms are provided for such as desire them.

HISTORY OF THE MEDICAL PROFESSION IN CANADA.—The descendants of the early doctors of Upper Canada will be interested to learn that there is being prepared an historical account of those pioneer practitioners, by Dr. Canniff, of Toronto, the author of "The Settlement of Upper Canada." The work will give an account of the several steps in legislation to secure a proper standing of the profession from the establishment of the Province of Upper Canada up to about the year 1850; 2d, an account of the proceedings of the Upper Canada Medical Board; 3d, a list of the medical men during that period, with bi-

ographical sketches. Dr. Canniff requests veteran medical men to kindly furnish him at once with information on the following points: 1, birthplace and date; 2, place of medical study and the degrees; 3, time of arrival in Canada; 4, places where he practiced; 5, incidents in his professional life; 6, marriage, children, and death.

CHICAGO POLICLINIC.—Dr. W. A. D. Montgomery has been elected Professor of Diseases of Children; Dr. M. L. Harris, Professor of Surgery; and Dr. Henry Hooper, Professor of Gynecology.

MEDICAL GRADUATES.—Following are the numbers of graduates from schools that have recently closed the session of 1888-89: Baltimore Medical College, 21; Starling Medical College, 28; University of Nashville and Vanderbilt University, 98.

MEDICAL EDUCATION.—At the annual meeting of the Board of Trustees of the Central College of Physicians and Surgeons of Indianapolis, held March 1, 1889, the following resolution which had previously been passed by the stockholders and faculty, received the unanimous vote of the members:

"That after the session of 1890 and 1891, the Central College of Physicians and surgeons require of each student who is a candidate for graduation, evidence of four years' study of medicine, and the attendance of three courses of lectures."

THE ANNISTON CITY (ALA.) MEDICAL SOCIETY met and organized on February 23, with Dr. H. Mabbett as President, and Dr. Bowcock as Secretary.

PROPOSED HOSPITAL FOR INEBRIATES IN MASSACHUSETTS.—A bill has been introduced into the Massachusetts Legislature providing for the establishment of a hospital for inebriates. This indicates a new development of knowledge and experience in regard to the treatment of habitual drunkards. Dipsomania is now distinctly recognized as a disease. The patient may have been culpable in inducing it; but, when it is once acquired, it cannot be expelled without the proper treatment. This treatment must be based on sound medical and moral principles. The fact that dipsomania is a disease is already conceded in the laws of the State which provide for the commitment of such persons to the insane asylums. But experience has shown that, while the law is right in recognizing the disease, its disposition of the victim is not fortunate or adequate. A large amount of testimony can easily be gathered from superintendents of insane hospitals to show that such institutions are not proper places for the commitment of dipsomaniacs or habitual drunkards. At the end of a few weeks, when the paroxysm of inebriety has passed away, the patient is apparently well. He is at least no longer insane in any proper sense. It is not difficult to procure an early discharge; and the patient goes forth only to renew his debauch at the usual interval, and is perhaps recommitted to the asylum. What he really needs is to be treated, not for insanity, but for drunkenness. The methods of treatment are not identical. An habitual drunkard needs to be restrained long enough to establish the physiological changes necessary to a permanent cure. He needs also to be brought under the constant pressure of moral influences which shall develop and strengthen the power of self-control.

Nor is a prison any more than the insane asylum the proper place to commit habitual drunkards who are not criminals. The drunkard who commits a crime against society while under the influence of liquor becomes amenable to the criminal law. The drunkard who has not in other respects a bad repute, but yields to the dominion of this form of self-indulgence, belongs to a different class. In both cases the aim of society should

be the same—the reformation of the victim. But the proper classification may lead to a distinction between them. The time will come, we trust, when all prisons will be regarded as moral hospitals. But that time has not yet arrived. A prison is still popularly regarded as a place for the infliction of punishment. Incarceration carries with it the stigma of criminality. There are those who feel that the drunkard or the opium-eater, who is simply guilty of a sin against himself, should not be placed in prison with those who are guilty of sins against society. We do not think this reasoning should be pushed too far. We believe that every man who yields to self indulgence violates not merely his obligations to himself, but obligations to society and posterity. And it may be shown that the drunkard who bequeaths the terrible consequences of his indulgence to his children has done vastly more harm by his life in the world than the man who steals a few dollars from his neighbor and is branded as a thief.

It is not necessary here, however, to press points of casuistry. We simply urge that this matter be approached in a practical way. It is a simple fact that a large percentage of inebriates may be cured if placed under proper conditions. These facts are amply supported by the testimony of medical men and of experienced temperance workers. It is further reinforced by the statistics of the most successful private inebriate asylums. But such asylums are not available to many of the poor, nor can they command those conditions which may be provided by State Institutions. The difficulty in private institutions is that the patient wishes to decide for himself when his cure is completed. His judgment does not agree with the judgment of his physician, but the latter has no power to restrain him. The bill before the Massachusetts Legislature grants a power of restraint over the patient extending to 2 years. It provides for the commitment of the inebriate under proper legal form and on sufficient medical evidence. It also protects the inmate against the possibility of unjust detention; and, should it become a law, as we trust it may, those inebriates who are now sent to insane asylums and many that are sent to reformatories would be committed to its care. The bill has been carefully drawn by medical and legal experts, and Massachusetts now has an opportunity of trying an experiment which ought not to be longer delayed. Every step in the classification of disease and crime is a step in advance. The new institution, if established according to this bill, will not be a prison or an asylum—it will be a hospital. Here the patient may be surrounded by every needed influence, physical and moral, until he has outgrown the disease which has mastered him.—*St. Louis Globe-Democrat.*

THE TREATMENT OF GLYCOSURIA.

Read before the Chicago Medical Society, March 18, 1889.

BY CHARLES W. PURDY, M.D.,
OF CHICAGO, ILL.

It is customary to consider glycosuria under two forms: *First*.—A milder manifestation of the disease in which only small amounts of sugar appear in the urine, and these often intermittently; while the general health of the patient suffers little or no disturbance. *Second*.—A more severe type of the disease characterized by excessively saccharine urine, great thirst, polyuria, emaciation, etc., leading more or less rapidly to extreme marasmus and death. The first form is chiefly of reflex origin, and hence its milder type and rarely fatal termination; while the second form is doubtless of central origin, and consequently more pronounced and serious in its consequences. In a systematic consideration of the management of glycosuria it is important that these two types of the malady be constantly kept in mind.

Physiological chemistry has shown us that glycosuria expresses itself chiefly through disturbance of the glycogenic function of the liver. Claude Bernard extended our knowledge a step farther, and showed that the elemental cause consists of some disturbance of the central nervous system, closely corresponding to the vasomotor centre. All attempts, however, to unravel the nature of this disturbance through the aid of morbid anatomy have proved thus far entirely futile. It is well to remember, however, that in careful scientific research, failure often teaches us valuable lessons, and, indeed, often furnishes useful information. The very fact that the study of morbid anatomy in glycosuria has failed to reveal uniform and tangible lesions of the central nervous system goes far to form a presumption that if lesions exist in these cases they can scarcely be sufficiently grave in themselves to cause fatal results. Our present knowledge of the nature and course of glycosuria is quite in harmony with this presumption; for indeed we find the cause of death uniformly to depend upon the perverted function of organs widely apart from the brain.

Moreover, if the perverted function of these organs can be corrected and held under control the patient may survive almost indefinitely.

Without entering into the discussion of the many theoretical questions with which, unfortunately, our knowledge of glycosuria is at present so deeply involved, let us more practically inquire, What facts have we at command upon which to base a rational system of managing the disease? We know that the chief expression of glycosuria is a perverted elaboration of the hydrocarbon foods in the liver, resulting in their conversion into grape-sugar. We know that the surcharging of the blood with large quantities of this sugar, not only gravely alters the nutritive qualities of the blood; but it is also liable to induce chemico-toxic changes in that fluid, which are dangerous to life. We know, in short, that the perverted elaboration of so large a proportion of the food supply as that of the hydrocarbonaceous, the saturation of the tissues with the resulting morbid products, and the necessary efforts at their elimination, lead to altered nutrition, emaciation, wasting of the vital forces of the economy, secondary disease of important organs; and to that complex of morbid processes that in glycosuria bring about exhaustion and death. Now, obviously, if we can succeed in cutting off completely the supply of such foods as are prone to faulty elaboration—for the most part the hydrocarbons—we shall not only arrest the perverted liver function; but we shall also save the system from the damaging effects of the morbid products poured into it through faulty elaboration of food, and thus practically arrest the regressive changes that lead to such grave results.

If we had to deal only with the purely hydrocarbon foods as the exclusive source of sugar production in the economy, our problem would be a comparatively simple one; since a thoroughly nourishing and sustaining diet can be furnished exclusive of these. But while the hydrocarbons are the chief, they are not always the only source of sugar production. Experimental investigation has shown that when animals were fed on purely nitrogenous foods—even for lengthy periods of time—a small amount of glycogen still continued to be present in their livers. In the most grave forms of diabetes, the "sugar-forming vice" of the organism

becomes so strong that the liver seems capable of splitting up a portion of the nitrogenous foods, and even of the albumenoids of the tissues, and of transforming a part of these into sugar. Fortunately such cases are for the most part long-neglected or advanced ones. Although much may be accomplished even here in retarding the disease, yet it may, as a rule, be considered progressive towards a fatal termination.

The sugar-forming powers of the organism in glycosuria are feeblest in their operation upon nitrogenous materials; indeed in the early stages of the disease it is probable that these always escape sugar transformation. Next in order come the green parts of certain vegetables, which very strongly resist sugar transformation. The hydrocarbons offer the least resisting power of all foods to sugar transformation, and of this class starch is the most dangerous element.

Practically then the more completely we are able to eliminate the hydrocarbons from the food supply in glycosuria, the more completely will we be able to bring and to hold the disease under control. Certain allowances must be made for individual idiosyncrasies, as well as for a few exceptional articles of diet, which experience has shown us are sometimes well borne—even when their classification would seem to contraindicate their use. To speak more accurately then, the more completely we are able to supply the system with that which it can appropriate as nourishment, and at the same time the more completely we can eliminate that which is convertible into sugar the more successful will be the treatment. Now, in view of the above facts, which I have endeavored to present as carefully separated from theoretical speculations as possible, it seems indeed strange that more earnest efforts are not made in the management of glycosuria—especially in the more pronounced types of the disease—to supply more nearly that diet upon which almost alone depends the improvement or cure of these cases. I shall first point out what seem to me the more prominent errors commonly made in dieting in the severe type of the disease, giving a list of the admissible foods; after which I shall note some of the liberties of diet that may be indulged in the milder reflex forms; and lastly, I shall refer to the influence of drugs over the disease.

First in importance comes the question of bread, some form of which containing starch is permitted in all the diet lists I have seen. Now I do not hesitate to state, without fear of successful contradiction, that all the so-called diabetic flours, breads, and cakes in the market of which I have any knowledge, are loaded with hydrocarbons. They are "a snare and a delusion," and have unquestionably shortened the lives of thousands. Most samples of gluten flour, from which the starch is claimed to have been eliminated—or nearly so—contain from 20

to 40 per cent. of starch. I saw in Dr. Pavy's laboratory in London a few months since an analysis of one of the so-called diabetic flours on sale in our markets, which showed the starch contents to be nearly 60 per cent. Long before I became aware of these facts I found that I could not control typical cases of diabetes if I permitted the use of commercial flours so-called "diabetic." I need scarcely add that with the above figures before me I have discarded them altogether.

The withdrawal of bread from the diet usually constitutes the most serious deprivation the diabetic patient has to encounter, although the appetite for bread is more largely a matter of taste and habit than of necessity. Some patients become quite reconciled to the change after a few weeks and do not mind it, but usually the craving for bread of some kind remains more or less strong, and will not be supplanted by the use of other foods. In the latter class of cases, if strict dieting be demanded, I permit the moderate use of bread made from almond flour as first practiced, I believe, by Dr. Pavy. The almond is absolutely free from starch, but contains about 6 per cent. of sugar. The latter may be eliminated by boiling the meal in acidulated water for an hour or so and then straining it. The almond meal is not on sale in the markets; the large percentage of its contained oil (50 per cent.) renders it unfit for keeping sufficiently long for commercial purposes. In my own practice I direct the meal to be made as required by means of mills especially constructed for the purpose. Almond flour, when beaten up with eggs, may be raised with the aid of a little baking powder, and baked in small tins in an oven, and the resulting bread is relished by most of my patients as equally palatable with ordinary bread. It should be borne in mind that almond bread, as indeed all substitutes for common bread, should be used in moderation; otherwise patients deprived of other luxuries of food fly to the permitted bread with an avidity seemingly born of the thought that it is indeed the "staff of life" instead of merely a substitute therefor. To make a substituted article of diet go further than the original one is more than is to be expected, even in these practical days, and yet I am led to believe that the failure in accomplishing this in the case of almond bread has led to its unjust condemnation by some in these cases.

The next question of importance in diet—and one upon which authorities greatly differ, is the propriety of the use of milk in diabetes. Dr. Donkin, perhaps the most enthusiastic advocate in its favor, published a book in 1871, which was devoted to the exclusive use of milk as a means of treating this disease. In England Dr. Donkin's so-called "milk cure" has met with few if any weighty supporters; on the contrary, many advocate the total exclusion of milk from the diet. My own experience in the use of milk in

the treatment of diabetes began nine years ago since which time I have made thorough and varied trials of it, both as an exclusive and as an adjunct diet. My conclusions are that milk is successful chiefly—perhaps only—in milder forms of the disease, such as I have termed reflex cases. Such cases are, as a rule, controllable by moderate limitations of diet, which offer greater range and nutritive power than does milk. In the more severe type of the disease I have repeatedly found when the diet was rigidly restricted, save in the use of milk, that the total exclusion of the latter without other change caused a prompt reduction, and often the disappearance of sugar from the urine.

Milk contains a very considerable amount of sugar (lactine), about half an ounce to each pint, and Dr. Pavy observes that this animal hydrocarbon "comports itself in the intestinal canal precisely as does grape-sugar." There can be little doubt, therefore, that in the more pronounced type of diabetes requiring a strict diet, milk should be excluded from the list.

There is a form of glycosuria that occurs in obese and over-nourished subjects, in which the amount of sugar in the urine is usually small, and probably largely due to the ingestion of more hydrocarbons than the system is able to appropriate. Such cases are benefited, and indeed often cured, by a course of fasting. The "milk cure" consisting of the exclusive use of skimmed milk is likely to benefit such cases because it is, in fact, a system of starving.

Skimmed milk alone is not sufficient to long maintain proper nourishment to the organism. In pronounced diabetes of central origin, where the assimilative powers of the system are weakened, and more or less emaciation has already set in, it would, therefore, seem absolute folly to confine the patient to skimmed milk, for under such circumstances death from inanition must be but a question of a short time. Sir Wm. Roberts records three cases which he subjected to the "milk cure" with the result that they all succumbed in a short time. My own experience is similar to Dr. Roberts', save that I ceased to use it as an exclusive diet after seeing my first patient rapidly sink under its employment. It is important to bear in mind that lactine is confined to the whey, and consequently the other derivatives of milk—as cheese, cream, curds and butter—are unobjectionable.

Another food of animal source contraindicated in diabetes is liver. The liver of animals contains considerable sugar, as might be expected, considering the glycogenic function of that organ. Not only should the liver of quadrupeds be avoided, but certain fish, especially oysters and the interior of crabs and lobsters, since they possess proportionately very large livers. It has been claimed that this precaution is more in keeping with theory than practice, but a sufficient answer is fur-

nished in the fact that analyses of oysters have shown as high a range as 10 per cent. of sugar.

The very wide distribution of starch and sugar throughout the vegetable kingdom renders our selection of food from this source limited indeed. In strict dieting we are obliged to avoid nearly the whole list of table vegetables. One class only are we at all safe in drawing upon—greens—and these with caution. Green vegetables fortunately consist mostly of cellulose and contain little, sometimes no starch or sugar. They are rendered still safer if boiled before being eaten; the hot water further ensuring the absence of starch and sugar.

The starch and sugar composition of vegetables varies somewhat. This variation depends much upon the degree of cultivation, and the nature of the climate and soil in which they are produced. As a rule, a high degree of domestic cultivation favors an increase of starch and sugar, while high temperature and sunny skies have an opposite tendency. Among the least objectionable vegetables may be mentioned spinach, lettuce, olives, cucumbers, mushrooms, Brussels sprouts, turnip tops, water-cresses, cabbage, cauliflower, and the green ends of asparagus. Nearly all nuts are unobjectionable, chestnuts forming an exception.

In the matter of beverages the diabetic patient will scarcely encounter very serious restrictions, since the range permitted includes most of those in domestic use, including many which fall within the line of luxuries. Among these may be mentioned tea, coffee, all mineral waters, pure spirits, as brandy, whisky, gin, and such wines as claret, Rhine wine and Burgundy.

Having briefly reviewed the food products applicable in glycosuria, I shall now enumerate the list I employ in dieting patients upon strict principles, as appropriate in the more severe type of true diabetes of central origin.

STRICT DIABETIC DIET.

Meats of all kinds except livers; beef roasted, broiled, dried, smoked, cured, potted, or preserved in any way except with honey, sugar, or prohibited vegetables. Mutton, ham, tongue, bacon, sausages. Poultry and game of all kinds. Soups made from meats, without flour or prohibited vegetables. Eggs, butter, cheese, pure cream, curds, oil, gelatine and unsweetened jellies. Fish of all kinds except oysters and the inner parts of crabs and lobsters. Bread, biscuits, and cakes made from almond flour. Spinach, lettuce, olives, cucumbers, mushrooms, water-cresses, green cabbage. Almonds, walnuts, Brazil nuts, filberts, butternuts, cocoanuts. Salt, vinegar and pepper.

Drinks, tea and coffee, mineral waters, whisky, gin and brandy, in moderation. Claret and Rhine wine.

In mild forms of glycosuria some additions may be safely made to the above diet, and often with advantage. Since in such cases the sugar-forming

powers of the organism are weaker ; or, in other words, the assimilative powers for sugar and starch are greater, it is only necessary to limit, *not to curtail* the hydrocarbons. It seems necessary, therefore, to have at hand to draw upon a supplementary list of foods, which contain but limited amounts of these agents. The selection from the supplementary list should always be made with care ; indeed, it should be almost as much a matter of experiment as rule, since we encounter wide differences in individual cases. Thus levulose—fruit sugar—is often well assimilated in the milder form of the disease, and this permits the inclusion of certain fruits in the supplementary list.

SUPPLEMENTARY DIET.

Cabbage, celery, radishes, cauliflower, green string beans, coldslaw, kraut, young onions, tomatoes, cranberries, apples if not sweet, milk in moderate quantities, and bran bread or gluten bread well toasted.

The discovery of saccharin has furnished us an admirable substitute for sugar, since this agent possesses a sweetening power nearly 300 times greater than that of sugar, and a flavor quite as agreeable and pleasant. The tablet form in which saccharin is now put up is very convenient for sweetening coffee, tea, and other beverages. Constant use of saccharin in practice for over a year has convinced me that it is entirely harmless in these cases.

The method of dieting diabetic patients is of scarcely less importance than the quality of the diet itself. In order to more accurately determine the effects of diet upon the disease, no so-called specific medicines should be administered until the sugar excretion is reduced as far as is possible by diet alone. Step by step the more objectionable foods should be cut off until sugar ceases to appear in the urine, or until we reach almost—indeed in some cases an absolute—animal diet. Of course, where patients have been enjoying all the luxuries of a diet range comprising our modern resources of food-supply and culinary arts, an abrupt change to a strict diabetic diet would carry with it more or less danger, and therefore such course is never advisable. *The first step* should consist in the exclusion of potatoes, sugar, and farinaceous foods, except leaving the patient the liberty of using a moderate amount of bread thinly cut and well toasted on both sides. With these restrictions the patient should continue without other changes for about two weeks. In the milder cases this "first step" in dieting will have caused a reduction of the sugar in the urine to relatively small proportions ; indeed, in some cases it completely vanishes. If sugar still appears in the urine—especially if in considerable quantities—under the above restrictions, we may know that the disease is at least of moderately severe type, and we should proceed to the next step in the diet.

This should consist in the exclusion of milk, and all vegetables save green ones. Greater care should be exercised in the use of bread ; white bread should be forbidden, and some substitute employed that contains less starch. Gluten or bran bread may be tried, but always toasted, as this alters its contained starch, so that it is not so readily converted into sugar.

After two weeks' adherence to the above restrictions, if sugar still appears in the urine beyond mere traces, we may be sure that we have to deal with the disease in its more severe type, and we must accordingly bring to bear against it all our resources of diet in the most strict form. Everything containing starch or sugar that can be avoided, should be strictly forbidden. This last step should be entered upon rather more gradually than the others. Milk, if previously permitted, should now be replaced by pure cream. Cabbage, celery, radishes and string beans should be exchanged for spinach, lettuce, water-cresses, olives and cucumbers. Lastly, apples, tomatoes and all fruits should be avoided, and, with the exception of almond bread, some nuts and a few greens, the patient is reduced to an animal diet. Upon these restrictions, properly carried out, we shall find a large proportion of diabetic patients cease to excrete sugar with their urine, and with this result nearly all the symptoms of the disease will disappear.

In exceptional cases, even after a fair trial of the above restrictions sugar still appears in the urine, but it rarely exceeds 1 per cent. Under such circumstances the patient should be placed upon an absolutely animal diet, at least for a time. It will be found that a strictly animal diet will often remove these last traces of sugar from the urine, and after its continuance for a longer or shorter time, a reversion to some of the less objectionable articles of the vegetable order causes no reappearance of sugar in the urine.

In accustoming the patient to the more strict form of diet, care should be exercised not to permit the stomach to be overloaded. The beneficial effects of temperate eating in glycosuria were very prominently illustrated during the siege of Paris, as Bouchard observed that sugar entirely disappeared from the urine of diabetics in whom up to that time it had persisted, even though they had been living on a carefully regulated diet. The diminution in the quantity of food, occasioned by its great scarcity during the siege, effected that which alteration in quality had failed to accomplish.

The more slowly food is submitted to the digestive forces, the more completely is it likely to become assimilated. Light meals frequently repeated is the better rule to follow, at least until the patient becomes accustomed to the change. It is important also that the diet be varied as greatly from day to day as the range of food in the list will permit.

I have repeatedly placed diabetic patients that were considerably under 20 years of age upon the strict lines of diet herein indicated, with the result of completely eliminating the sugar from the urine for weeks and months together, and without resort to medication. Thus it may be seen how much may be expected from proper dieting, even in cases that we are forced to consider as ultimately hopeless ones.

By way of illustration—a year ago this month a lad of 18 years came to me from a distant State with a history of diabetes of over a year's standing. His symptoms, as is usual in such cases, were great thirst, morbid appetite, polyuria, and advancing emaciation, with a very considerable amount of sugar in his urine. His physician at home had put him upon a diet scarcely so limited as the "first step" laid down in this paper, and but a slight check was put upon the disease. I gradually restricted his food allowance until it conformed to the strict diabetic diet already laid down. His thirst gradually subsided, the quantity of urine diminished, and at the end of six weeks no trace of sugar was to be found in his urine, and he began to regain his lost weight. Under a continuance of this course the urine remained normal in quantity and free from sugar for about three months, when he returned to his home with directions to follow as closely as possible the course that had so greatly benefited him. This case may be fairly ranked among the most unpromising ones, chiefly on account of the patient's age; for it is a rare exception to meet with a case under 20 years of age in which the disease does not rapidly prove fatal unless the patient be very strictly dieted.

It may be said of glycosuria in general that its severity is usually in inverse ratio to the age of the patient. The youngest diabetic I have seen came under my care a short time since, in the person of a little boy 3 years and 2 months old. In this case the polyuria was so pronounced that a nurse had to be provided to attend him at night, as he "wet the bed" from six to eight or more times each night. It may be of interest to note that he was put upon an animal diet, including milk, which soon lessened his polyuria so that the patient did not urinate during the whole night. I believe milk is more easily assimilated by children than by adults; at any rate it seems to agree better with them in these cases; and this is very fortunate, since we are almost driven to its use in diabetes of tender age. As a rule, in patients under middle age, we shall be obliged to bring to bear against glycosuria all our resources of dieting in the more strict form. I have met with an exception to this rule in the case of a Jewess, 29 years of age, in whom moderate restrictions of diet have kept the urine practically free from sugar for the past year and a half, only exceptional traces having appeared

occasionally. It has been remarked by several observers that diabetes is frequent among Hebrews, and that in them the disease is always of mild form. My own experience tends to confirm the latter statement. I have, indeed, at the present time, three cases in Hebrew women under treatment, and they are all of mild form.

For the most part the milder forms of glycosuria are met with in people that have passed the age of 40 or 50 years. In this class of cases our resources against the disease are always more effective; indeed, one or two years careful dieting not infrequently leads to permanent cure.

It remains, to speak of the medicinal treatment of glycosuria, and I may as well state frankly at the beginning that I have little faith in the curative power of medication over the disease, while on the contrary I am satisfied that the use of drugs in these cases is often productive of harm. My conclusions upon this point have been reached through separating the dietetic from the medicinal treatment, and then comparing the results of each. When a system of diet and medication are employed together from the beginning, the benefits accruing from diet may be attributed to the medicines, while the unfavorable influence of medication may be attributed to the disease. Our faith has become so supreme in the efficiency of medication in these days, that we are apt both to permit ourselves to be misled in its favor, and to overlook its possible injurious effects.

Of the various drugs that have been recommended in glycosuria, opium, perhaps, maintains its reputation best and has become the most popular. Opium undoubtedly tends to restrain the excretion of sugar in these cases, but the doses necessary to accomplish this result are so large that the drug is likely to induce constipation and impaired digestion, and thus any good accomplished through its use is more than counterbalanced by resulting evil. I have recently gone over this ground very carefully in a series of trials systematically conducted. Three cases were selected, in each of which the sugar excretion had been reduced by strict diet to about 1 per cent. They were all typical cases of true diabetes of central origin; and no little pains had been expended in reducing the sugar to so small a percentage, and maintaining a good general condition with excellent digestion and assimilation. Under gradually increasing doses of opium the sugar excretion was reduced somewhat in all the cases, but sooner or later constipation, loss of appetite, or nervous disturbances compelled the discontinuance of the drug without exception. This has always been my experience in the use of opium in glycosuria; nor have I found any material advantage in the use of morphia, its bimeconate, or the use of codeine. They all comport themselves much the same as does opium when used in equal physiological doses.

Ergot is probably the next most popular drug employed in the treatment of glycosuria. In the necessarily large doses required to effect the disease it is unsuitable for lengthy periods of administration. Its controlling power over glycosuria is very feeble and uncertain, and on the whole it may be regarded as unworthy of much confidence.

Bromide of arsenic and syzygium jambolanum have recently been highly lauded in the treatment of glycosuria. I have known the former to be administered in the largest doses (25 drops Gilliford's solution), during which time the patient continued to excrete urine that contained 30 grains of sugar to the ounce. Upon withdrawing the bromide of arsenic and placing the patient upon a restricted diet, I had the satisfaction of seeing the sugar speedily reduced to 2½ grains to the ounce. I have administered jambul to a number of my patients, but without noticing any favorable change that I could fairly ascribe to its use. A number of other drugs have been more or less highly extolled for their alleged specific influence over glycosuria. Among these may be mentioned iodoform, bromide of potassium, iodide of potassium, arsenic, sodium phosphate, nitrate of uranium, salicylic acid, picric acid and Calabar bean. There does not, however, appear to be sufficient evidence in favor of any one of these to entitle it to any degree of confidence. Carefully discriminated from the benefits derivable from dieting, these drugs are probably nearly inert so far as their influence over glycosuria is concerned.

The legitimate field of therapeutics in glycosuria becomes practically narrowed down to the treatment of its accompanying symptoms, and upon this point but few words will be here added. It has already been stated that disordered digestion is so frequent in glycosuria as to constitute it an accompanying rule. Indeed, many of the milder cases owe their origin without doubt to this cause. The digestive and assimilative functions should therefore receive especial support through such agents as experience has taught us prove the most efficient. Among these may be mentioned, pepsin and the vegetable bitters—and especially strychnia. The latter I have come to regard with increasing favor.

Constipation, so frequent an accompaniment of glycosuria, should be especially guarded against, as this condition reacts very markedly in enfeebling the digestive and assimilative powers. I have an especial preference for the natural alkaline purgative waters to meet such requirements, since they relieve the over-acid condition of the intestinal canal so common to the disease. Friedrichshall or Sprudel—or the salt made by the evaporation of the latter—given before breakfast, in hot water, seem especially appropriate. In middle-aged people inclined to stoutness and over-eating, a course of purgation by either of these agents often proves highly beneficial.

The various nervous disturbances accompanying glycosuria are, on the whole, perhaps best met by the use of bromides—especially that of sodium or lithium. It is not uncommon to meet cases of glycosuria complicated by anæmia. When pronounced, this condition is frequently attended by œdema of the extremities, and under such circumstances the liberal use of iron and arsenic is attended by excellent results. The appearance of multiple boils is not uncommon in glycosuric patients; a complication generally considered ominous of approaching danger. I have seen a disappearance of this complication in two weeks under the use of quinine—8 to 10 grs. daily—after having resisted other measures for nearly three months.

The most dangerous, and certainly the most rapidly fatal, of all the complications of glycosuria is that of Kussmaul's coma—sometimes called acetonaemia. Since the treatment of this complication has thus far proved so unsatisfactory, a knowledge of the conditions commonly leading thereto should be borne in mind, in order to guard the patient against it. Constipation, mental emotion, and fatigue seem especially to predispose to this complication, while a highly acid state of the urine often precedes it. I have repeatedly, in these cases, observed sudden death by coma to constitute the penalty of a hunting expedition, or long railway journey entailing unusual fatigue. If the early indications of approaching coma are observed, stimulants and hot baths should be resorted to without delay. It is believed that diabetic coma is brought about by some toxic agent in the blood, perhaps derived from alcoholic fermentation of glucose. Whether this be acetone, or some other agent, we are warranted by certain facts in believing that it is of an acid nature and, therefore, large doses of alkalies seem the most appropriate remedies to employ. An ounce of tartrate or citrate of soda dissolved in a pint of water may be given three or four times a day. The intravenous injection of sodium carbonate, with chloride of sodium, is strongly advised if coma has already become established. Under the latter circumstances, however, recovery is extremely rare under any form of treatment. On the whole, then, promising results are only to be expected by attempts at warding off the attack through such measures as have already been suggested.

In concluding what has been intended as a practical review of the management of glycosuria, it seems desirable to emphasize the immense importance of careful dieting as greatly outweighing all our other resources combined. This fact should be strongly impressed upon the patient from the beginning. He should be taught to rely little upon medication, and the most effective means of doing this is to show him how much can be accomplished by careful dieting alone. When he

has once learned through experience that the amount of sugar in his urine always bears a direct ratio to the prohibited foods indulged in, he is less likely to overstep the proper limits imposed. With his thirst, polyuria, and other discomforts relieved—a sure sequence of careful conformance to the rules—unless he be greatly lacking in intelligence and gratitude, he will cheerfully submit to the conditions imposed, since he will see and feel how greatly he is indebted to them.

163 State St., Chicago.

AN INTRODUCTION TO THE STUDY OF PNEUMONIC FEVER.

BY EDWARD F. WELLS, M.D.

FOURTH PAPER.—PREVALENCE.

Pneumonic fever "is one of the severest, most common, and in cold and temperate climates, is productive of more deaths than any other acute disease,"¹ and "is, next to phthisis, the greatest enemy of mankind."

The prevalence of a disease may be studied in various ways, *c. g.*, by considering; α . the annual mortality in relation (1) to the population, (2) to the deaths from all causes and (3) to the deaths from certain specified causes, and β . by comparing the annual mortality to (1) the population, (2) to that from all causes and (3) to that from specified causes.

Pneumonic fever is responsible for an annual mortality of 1.27 per 1000 of population. This estimate differs somewhat from those arrived at by Sanders,³ 1.38; Hirsch,⁴ 1.49; Ziemssen,⁵ 1.53, and Osterlen,⁶ 1.85. Inasmuch, however, as the magnitude of the figures with which I deal is much greater than that of either of these statisticians and are derived from a wider field, I am persuaded that my results approach nearest the truth. It is also the cause of 7.1 per cent. of all deaths. Sanders' estimate is 5.9 per cent., Juergensen's⁷ 6.6 per cent., and Paton's⁸ 17 per cent!

The following table shows the material from which my estimate has been derived. The magnitude of the numbers employed, the wide distribution of the points of observation, and the number of years embraced in the calculation will go far towards eliminating those errors incidental to all statistical inquiries.

TABLE III.—SHOWING PREVALENCE OF PNEUMONIC FEVER.

¹⁷³ Report State Board of Health, 1886.

Osterlen¹⁶⁰ gives the proportion of deaths from pneumonic fever and phthisis as 1.85 and 2.50 per 1000 of population, respectively. Ziemssen¹⁷¹ places them at 1.70 and 3.20 respectively. Juergensen¹⁷² gives the proportion as 1.70 to 3.23 in London; 2.52 to 3.82 in Paris and 1.13 to 2.96 in Berlin. Klinger¹⁷³ found that during the five years, 1868-72, pneumonic fever caused more deaths than phthisis in Bavaria, the proportion being 2.2 and 2.1 per 1000 persons. In Christiania¹⁷⁴ the ratio is 1.16 to 2.85.

In estimating the morbidity of this disease we are met by a very practical difficulty, and that is the impossibility of obtaining statistics which fairly represent the whole body of the population. The available material has all been derived from particular and exclusive classes—such as army and navy returns. That these cannot afford averages applicable to the generality of the inhabitants of the world is self-evident. However I have made use of such materials as are obtainable, and from them constructed the following table:

TABLE V.—SHOWING MORBILITY OF PNEUMONIC FEVER.

AUTHORITY.	Persons.	Cases.	Per 1,000
Circular No. 6, War Dep't., Washington, 1865.	934,444	31,527	33.8
Fitzsimmons, Lancet, 1884, Vol. i, p. 142. . . .	1,465	11	45.2
Forry, Mortal. U. S. Army, Washington, 1840.	3,138	22	7.0
Hermann, Lungenentzündung, etc., S. 13. . . .	59,922	399	6.7
Laveran, Mal. des Armées, Paris, 1875, p. 28. . .	53,137	235	4.4
Tulloch, Mortal. British Army, London	542,427	15,860	29.2
U. S. Naval Reports, 1880-St.	21,353	80	4.2
Totals and averages	1,637,886	48,130	29.9

From this table we find that the average annual morbidity of pneumonic fever is 29.9 per 1000 inhabitants.¹⁷⁵ This is somewhat in excess of the amount given by Forry¹⁷⁶ and quoted with approval by Lee¹⁷⁷ and Drake,¹⁷⁸ viz., 23 cases per 1000 of population. I am convinced, however, that both these estimates are excessive, due to the fact that soldiers are more liable to this dis-

Means of totals		1.5	2.4	.9	1.4

The annual prevalence of pneumonic fever in any given locality will vary from time to time, within wide limits, as shown in tables VIII and IX.²⁰⁷

Huss²⁰⁸ found the admissions for pneumonic fever into the Seraphim hospital of Stockholm during sixteen years to vary from 6.5 per cent. to 15.4 per cent. of internal diseases. His statistics give a mean of 10 per cent. and a fluctuation of 8.9 per cent.

THE DETECTION OF THE BACILLUS TUBERCULOSIS, TECHNIQUE.

Read before the Chicago Medical Society February, 18, 1889.

BY FRANK BILLINGS, M.D.,
OF CHICAGO.

The form of the bacillus tuberculosis is not characteristic, and it cannot, therefore, be differentiated from other pathogenic and non-pathogenic bacteria by its form alone. It is a very thin bacillus, about 2 to 5 micromillimetres in length (from one-quarter to one-half the diameter of a red blood-corpuscle). It is usually slightly bent.

Like all protoplasmic cells it has an affinity for the aniline colors, and its reaction to these colors is characteristic when the aniline is combined with a mordant.

To elicit the characteristic reaction of the bacillus to the aniline colors it is necessary to proceed in a methodical manner. The instruments used, forceps, needles, etc., should be clean, sterilized by heating in a gas or other flame. The cover-glasses and slides should be cleansed in fine alcohol.

The material supposed to contain the bacilli should be collected in a clean vessel, and when collected should be protected from contamination by the air, etc.

The material should be spread in a very thin layer upon a cover-glass, by means of a needle, or by placing a small amount upon one glass and then pressing another cover-glass upon the first, thus making a thin layer upon the two cover-glasses. The thin film is then allowed to dry upon the cover-glass, or the drying may be hastened by warming it over a gas flame. Then, when dry, by passing the cover-glass quickly two or three times through the flame, the albumin usually present in the medium, fixes the film upon the glass.

The cover-glass is now ready for the aniline dye. One may use any color, but aniline violet, methyl blue or fuchsin is usually employed. Fuchsin is the most often used, because its bright red renders the bacilli more prominent to most observers; and, too, one may use with it, better than with the other colors, a contrast color for the ground substance on the cover-glass.

The color used must be combined with a mordant, which so fixes it in the bacillus of tuberculosis as to render it very much less susceptible to the bleaching effects of the mineral acids, while it does not so affect other bacteria, with but two exceptions, which I shall mention later.

There are several substances that may be used as a mordant: aniline water, carbolic acid, tannic acid, and others. Aniline water was first used, and is still by some, but the mordant now in common use, and the one used by Prof. Koch, is carbolic acid. It has the advantage over aniline water that a solution of it with the color may be kept indefinitely, while the aniline water solution must be made each time it is used.

The following solution of fuchsin (Ziehl & Neelson) is a satisfactory one in every way:

Take of Fuchsin 1 part,
Acidi carbolic 5 parts,
Alcoholis 10 "
Aque distillate 100 "
Mix in the order given.

A few drops of the staining fluid are placed upon the cover-glass, held in a forceps with the film upwards over a gas or alcohol lamp flame until the solution boils or gives off steam. It is then washed in water and is ready for the process of bleaching.

For bleaching, any of the mineral acids may be used. A 25 to 33 per centum watery solution of

²⁰⁶ For further information on this subject consult Huss, op. cit., Juergensen, op. cit., Fritsch, Erlangen Diss., and others.

²⁰⁷ No effort has been made to render these tables exhaustive.

²⁰⁸ Op. cit., S. 63.

hydrochloric, nitric or sulphuric acid is used. Koch prefers nitric acid, his laboratory assistant uses sulphuric, while at Vienna hydrochloric is chiefly used. It is probably immaterial which acid is employed.

The stained cover-glass is immersed in the acid solution for a moment, then in a 70 per cent, water solution of alcohol, and finally washed in water. The immersion in acid, alcohol and water, successively, being repeated until the color is almost or quite bleached. This process leaves the bacillus tuberculosis colored red, while the ground substance and all other bacteria, with the two exceptions mentioned, are bleached. The mordant used enables the bacilli of tuberculosis to retain the color. Too long immersion in the acid will also overcome the action of the mordant and render the examination *nil*. The cover-glass should be finally thoroughly washed in water to remove all acid, otherwise the slight amount of acid remaining will gradually fade the color and in a few months the preparation will become worthless.

The cover-glass may now be mounted on a slide in water or glycerine, or, after drying, in Canada balsam. One may, however, use a contrast color—methyl blue for the ground work. It is only necessary to float the cover-glass, with the film downward, upon a 1 to 2 per cent. watery solution of the methyl blue for five minutes. The excess of blue color is washed off with water, the cover-glass dried and mounted. The bacilli of tuberculosis will be seen stained red and other elements will be blue.

For tissue containing the bacilli it is necessary to immerse the sections for from 12 to 24 hours in the fuchsin solution. They are then decolorized by immersion in the acid solution, the alcohol, etc., until only a faint redness remains. The sections are then dehydrated in alcohol and cleared up in the oil of cloves. When mounted the bacilli are seen red, the tissue decolorized. The methyl blue may be used as a contrast color, also, for sections.

To easily detect the bacilli so prepared, one should have a microscope magnifying at least 450 diameters; however, the bacilli may be seen with a less powerful glass. An ordinary stand and substage will do for cover-glass preparations, but an Abbé substage condenser is a decided aid to the discovery of the bacilli in cover-glass preparations, and it is absolutely necessary in examining sections.

The discovery of the bacillus tuberculosis in the excretions, secretion or exudates examined is positively diagnostic of a tubercular disease. When it cannot be detected its absence is not of much diagnostic value, for it may be present in such small numbers as to render its detection difficult or impossible. When it is not found readily repeated examinations of material collected on

different days must be made to make its absence of any worth as a negative sign.

The bacillus is most easily detected in the sputa of tuberculosis pulmonum. It is most difficult to detect in the blood, even in cases of acute general tuberculosis.

It is not usually difficult, as a rule, to detect it in the exudates into serous cavities; as in tubercular pleuritis, tubercular peritonitis and tubercular synovitis. I have found the bacillus in the contents of a distended Fallopian tube.

In tubercular disease of bone it is usually present in the cheesy infiltrate, but is difficult to find in the pus from sinuses in tubercular diseases of bone.

In the urine the bacillus is difficult to detect because of the bulk of urine and the decomposing effects of the urine. *Then the preputial and labial smegma bacillus* gives the same color reaction as the tubercle bacillus, and its form is so nearly like the bacillus of tuberculosis that it cannot be differentiated from it with the microscope. The presence, therefore, of a bacillus in secretions from the genitals, giving the color reaction and presenting the form of the bacillus tuberculosis is not here, as it is elsewhere, a positive sign of tuberculosis.

In tubercular disease of the skin and mucous membranes the secretion therefrom sometimes contains the bacillus. Sections made from tissue taken from tubercular ulcers usually yield the bacillus.

The bacillus of leprosy is nearly like the tubercle bacillus in form, and it gives the same color reaction. The clinical course of leprosy is so distinct, and the disease is so rare in this climate that it is not difficult to exclude it when considering a tubercular disease.

No. 235 State Street.

COMPLETE REMOVAL OF THE UTERUS AND ITS APPENDAGES FOR FIBRO- CYSTIC GROWTH.

BY H. C. PEARCE, A.M., PH.D., M.D.,
PROFESSOR OF OBSTETRICS, COLUMBUS MEDICAL COLLEGE,
COLUMBUS, OHIO.

Reported by T. M. TALBOT, A.M., M.D.

About January 1, 1888, Dr. Pearce, of Urbana, Ohio, was consulted by Mrs. C., æt. 36, in reference to an abdominal enlargement. On examination a globular body, the size of a foetal head at birth, was found in the right hypogastric region. Cystic disease of the right ovary was diagnosed. The tumor being small and the patient anæmic and in poor general health, noninterference for the present was advised. The patient was put upon bark and iron, and a general tonic treatment. Under this treatment she increased in strength and health, but with this improvement

there was a rapid increase in the growth of the tumor.

August 1, 1888, the patient again consulted Dr. Pearce. The tumor now filled the entire abdominal cavity, reaching up to the ensiform cartilage. The patient was nervous and irritable, and owing to the great distention of the abdominal muscles, she was suffering intensely from neuralgia at the tendonous insertions of these muscles. An immediate operation for the removal of the tumor was advised, but the patient, being of an exceedingly nervous temperament, could not make up her mind to undergo an operation. Accordingly, in the hope of obtaining relief otherwise than by operation, she consulted surgeons in both Cleveland and Cincinnati. These advised immediate removal of the tumor.

Meanwhile the tumor grew larger, and the patient grew weaker and more emaciated. It was not until death seemed imminent that she consented to an operation.

On November 5, 1888, assisted by Drs. J. H. Ayers, I. W. Goddard, H. M. Pearce and T. M. Talbot, Dr. Pearce operated at the home of the patient. This home, by the way, was a comfortable and commodious house. A room was selected with a view to size, light and ventilation. It was heated by an open grate, and received light from the west and south.

Before beginning the operation the temperature of the room was raised to 80° F. The patient was then etherized and placed upon the table. The abdomen was washed thoroughly with soap and water, then shaved, and finally washed with a 5 per cent. solution of carbolic acid.

The operation was begun by making an exploratory incision, two and one-half inches long in the median line, about half-way between the umbilicus and the symphysis pubis. Examination revealed a large fibro-cystic tumor of the uterus, strongly adherent to the right abdominal wall and surrounding tissue, and which had grown from the uterus and extended up to the ensiform cartilage.

The primary incision, being too small to make a complete examination, was increased to three and one-half inches. The ovariotomy trochar and cannula was then introduced, but the cyst could be only partially emptied of its fluid contents. The cannula was reintroduced at different points, but the fluid still remained to a considerable extent. Further examination showed the cyst to be divided by thick fibrous walls into three principal compartments. Each of these compartments was divided into numberless compartments or cysts by fibrous bands extending in all directions from the walls of the principal cyst. This condition, of necessity, rendered complete evacuation of the fluid contents of the tumor impossible. Accordingly the mass was loosened

from its posterior and lateral adhesions, and with difficulty it was drawn out of the original opening of three and one-half inches. After bringing out the sac or fibrous mass it was found that the growth had begun at the junction of the body of the uterus with the cervix—the point known as the isthmus. The growth enveloped the entire body of the uterus, and involved and completely surrounded both ovaries and broad ligaments. It was bound down laterally and posteriorly by fibrous adhesions that were difficult to break up, and which left a large bleeding surface within the cavity of the abdomen. These were unlooked for complications; and it left but one of two courses to pursue, viz.: the return of the mass entire or the removal of the tumor, including the uterus and all of its appendages.

The latter procedure was resolved upon, and carried out in the following manner: A Spencer Well's clamp was placed just below the junction of the body and cervix, and then tightened as much as possible without severing the parts. All the arteries supplying the broad ligaments and uterus were then tied with silk braid. This being done, the entire mass, tumor, uterus, and appendages was removed by cutting it off just above the clamp. The mass weighed thirty pounds.

The abdominal cavity was now thoroughly washed out with water, previously boiled and cooled to a temperature of 100° F. Several silk-braid sutures were passed through the abdominal walls, including the peritoneum; but before trying them a half-inch glass drainage tube was introduced into Douglas' cul-de-sac, and the peritoneum brought together by continued catgut suture. The ends of the deep suture were then tied, thus completely closing the wound except where the tube and clamp were.

The cavity was again washed out with warm water until the water came away clear. The incision was dusted over with powdered iodoform, and covered with silk isinglass plaster, moistened with a 5 per cent. solution of carbolic acid; over this plaster was placed a layer of iodoform gauze, then a layer of absorbent cotton, and all were held in place by a tight binder.

In this condition the patient was put to bed, and rubber bottles, filled with hot water, were placed to the extremities. Although the operation was quite tedious, lasting almost an hour, there was little apparent shock. This was very remarkable, when we take into consideration the frail and nervous condition of the woman, the nature and extent of the operation, together with the extensive adhesions of the tumor to the walls of the abdomen.

Twelve hours after the operation the temperature rose to 99.5° F., and the pulse to 120; eighteen hours after the temperature was 100° and pulse 135. At the end of thirty-six hours

the temperature was 100.5° F. and pulse 115. The temperature remained thus for five days, but the pulse dropped to 98. From this time on the temperature and pulse were practically normal.

The subsequent treatment is that to which especial attention is called. At the end of eighteen hours all the dressings were taken off, and the accumulated fluid removed as follows: A flexible rubber tube, about the size of a No. 12 soft rubber catheter, was attached to the nozzle of a syringe; the free end of this tube was passed in the drainage tube to Douglas' cul-de-sac, and the fluid drawn up into the syringe. The fluid thus removed amounted to about three ounces, and was sanguineous and very foetid in character. After the removal of the fluid the cavity was thoroughly washed out with water previously boiled and tempered to 102° F. The remaining water was withdrawn by means of the syringe as before described. No antiseptics were added to the water, nor were any antiseptics at any time used within the cavity of the abdomen. This mode of treatment was followed out twice in every twenty-four hours as long as this foetid fluid, before mentioned, accumulated in the cavity—which was twenty-two days.

On the twenty-second day the clamp came off, leaving a clean healthy-looking stump of the cervix. The sutures that still remained were removed, the glass drainage tube taken out, and a small rubber drainage tube was substituted. This tube was left in for one week. The syringe and a smaller rubber tube was used to draw out whatever pus accumulated, and the cavity washed out as before—though now once a day.

Particular mention is thus made of the washing out process, not because it is new in such cases, but because of the frequency with which it was employed. That this frequent and complete irrigation of the cavity has been of the greatest utility in this case is evidenced by the fact, that during the whole time, though removal of the tumor and uterus left a large suppurating surface within the cavity of the abdomen, there was little rise of temperature, and no tympanites nor tenderness over the abdomen.

The diet during the first three weeks was almost exclusively milk, which was taken cold and in liberal quantities. Since the first four weeks the diet has been somewhat liberal and varied. The other treatment has been such as is customary in ordinary abdominal sections.

The patient's recovery, owing to her emaciated and weakened condition prior to the operation, has been slow but steady. The wound has closed, leaving a smooth cicatrix about two and one-half inches long. The patient's appetite and general appearance have improved very much since the operation, and she has gained very rapidly in flesh. Her recovery is complete and very satisfactory.

MEDICAL PROGRESS.

A METHOD OF GENERATING NEUTRAL FUMES OF AMMONIUM CHLORIDE OR BROMIDE FOR INHALATION has been devised by DR. PATRICK WILLIAM MAXWELL, of Dublin. The instrument is made by Messrs. Anderson and Adams, 68 Grafton St., Dublin. It consists of a wide piece of glass tube, like the cylinder of an ordinary glass syringe, placed horizontally on two wooden uprights. About 15 grs. of ammonium chloride are introduced by a spoon through the wide end of this tube, and are placed in a little heap in the centre. The base is then lightly stopped with cotton wool. A lighted spirit-lamp, placed below the tube volatilizes the salt. A piece of india-rubber tubing with a glass mouthpiece is attached to the narrow end of the tube, by means of which the fumes are inhaled. A current of cold air rushing in by the large end of the horizontal tube mixes with the fumes and reduces their temperature, so that they are not more than slightly warm. These fumes are perfectly neutral from first to last, as is proved by passing them through red or blue litmus solution. Even phenol-phthalein does not become colored. There is also no free chlorine, for starch paper is unaffected. In the course of the inhaling tube is placed a glass bulb filled with glass wool moistened with water. This prevents the fumes from being too dry. Besides being perfectly neutral the fumes supplied by this instrument have the advantage of containing more ammonium chloride than is contained in the same volume of fumes from the ordinary inhalers.

When it is desired to apply the fumes to the middle ear a tube rather longer than the ordinary one can be attached to an Eustachian catheter, and the fumes pumped in by an india-rubber hand-ball fitted to the larger end of the horizontal tube.

The fumes, if desired, can be medicated by oil. pin. sylvest., eucalyptus, etc., by dropping about 5 ℥ of the oil upon the wool at the wide end of the tube.

As the iodine and bromine salts seem, when given internally, to have a greater selective affinity for the nose and throat than the chlorides, it occurred to me to try whether their ammonium compounds could be volatilized for inhalation. In the case of iodide of ammonium I found that though the greater part was volatilized as such, still it was mixed with so much free iodine and ammonia as to be very irritating and quite unfit for inhalation. In the case of bromine of ammonium, when only a moderate heat is used, the salt volatilizes unchanged, but as the temperature rises the odor of bromine can easily be detected in the fumes. Its presence can also be shown by its blueing starch and iodide paper. It was natural to expect, at least an equal amount of free am-

monia. Red litmus was not changed, but phenolphthalein gave a slight red. Ammonia is therefore present, but only in very small quantity. The quantity of free bromine must also be very small, as none of the patients who have as yet used these fumes have found them irritating. If the glass-wool is wet with an aqueous solution of resorcin of about 20 grs. to the $\frac{5}{8}$ j, all free bromine will be absorbed from the fumes. All ammonia is also, as already stated, absorbed by the water, so the fumes may be said to be neutral and pure.

The action of bromide of ammonium fumes seems to be very similar to that of the chloride. The bromide seems to draw more fluid from the mucous membrane, its greater osmotic effect being due probably to its greater molecular weight; it seems to have a sedative action on the mucous membrane of the entire nose and throat. This has been observed for some time as regards the pharynx. As the internal administration of the bromides is occasionally useful in tinnitus, I have thought it worth while trying its effect locally by blowing the fumes into the middle ear. Of course I do not suppose that this would benefit tinnitus of nervous origin, but it might be useful where congestion of the middle ear was the cause. As yet I cannot speak positively as to its effect in this way. I have, however, at present three cases of chronic catarrh of the middle ear with tinnitus which have resisted all the usual remedies. Each of these patients experiences a temporary diminution in tinnitus after applying the fumes through the catheter.¹ The strongest hydrobromic acid (33 per cent. gives off no vapor. I failed to produce any fumes by drawing air through such a solution and mixing it with ammonia. It is, therefore, evident that the ordinary apparatus for producing the chloride would be of no use for generating the bromide of ammonium.—*Dublin Journal of Medical Science*, March, 1889.

TINCTURE OF STROPHANTHUS.—DR. HERMAN HAAS has made a careful study of the action of tincture of strophanthus upon the visible, tactile, and graphic cardiac impulse. Fraser's tincture was used in doses of ten to thirty, or even up to fifty drops. No dangerous symptoms or cumulative action appeared, the appetite improved under its administration, which is contrast to digitalis in many cases. With other observers, he found the pulse slowed, and the patients improved under its use. As a diuretic it was successful in cases in which digitalis had been without avail. In order to observe the effect of strophanthus on the cardiac impulse only, three patients were used who showed a cardiac impulse which could be recognized by the eye and hand, when the patient was lying down; care was taken to observe the effect of a sitting posture or

standing upon the cardiac impulse; curves of both the cardiac impulse and the respiration were taken at the same time.

Before giving any dose it was necessary to study carefully the cardiograms characteristic of that individual. After this had been done, thirty to seventy drops of tincture of strophanthus were given, distributed over one or two days; curves were then taken for several successive days. After the effect of the new drug had passed off, it was repeated, and after a sufficient number of observations had been taken, and an interval allowed, digitalis was given, and the cardiograms of the two drugs were compared.

The results of the observations in all of the above (more than twenty cases) were very similar. It seems that five hours after the administration of tincture of strophanthus the character of the apex beat changes, it becomes ten to twenty beats slower per minute; the heart beat is quieter, and the impulse is weaker. The softening of the blow in the intercostal spaces is noticeable both to eye and finger, as well as to the open hand applied to the chest. In all cases in which there was not considerable hypertrophy of the heart, its lessened activity rapidly went so far that the point of cardiac pulsation was found only with difficulty, or not at all. This action was observed in all cases for a longer or shorter time, according to the dose or the amount of hypertrophy.

Dr. Haas considers the action of strophanthus to be one that diminishes the activity of the heart's muscle, as well as of the muscular layer of the blood-vessels; an action, in other words, not similar to that of digitalis, but directly the opposite. He thinks it doubtful in the light of his observations, if strophanthus increases the blood-pressure, notwithstanding Fraser's observations showing that the heart's muscle is stimulated to make stronger contractions under the influence of this drug.—*Deutsches Archiv für klinische Medicin*, vol. xliii, p. 353.

TREATMENT OF CHRONIC PHARYNGITIS.—In an admirable article by PROF. B. FRÄNKEL, of Berlin (*Therap. Monats.*, Nov. 1888), stress is judiciously laid upon individualization of treatment to suit individual cases, instead of routine measures adopted for universal use. Thus treatment suitable for hypertrophic cases injures atrophic cases, and *vice versa*, while the management of the transitional stages demands an experienced judgment. Precedent disease of the naso-pharyngeal region and of the nasal passages requires topical treatment at the same time; and its relief by such measures is sometimes followed by spontaneous recession of the morbid processes in the oropharyngeal region. At the same time it is incorrect to attribute general pharyngeal catarrh to precedent disease of the nose and of

¹ The condition of one patient remains unchanged. The other two are much improved (Feb. 16th).

naso-pharynx, as has been so much urged by several American writers.

The first indication in treatment is that of the cause. Hence, obstructions in the nose must be combated to restore nasal respiration, and disorders of the mouth and teeth must be corrected. The surroundings of the patient must be modified when at fault, as well as any injurious avocation, habit, or mode of diet or of living. Proper clothing and underclothing are necessary to secure immunity from susceptibilities to cold. As to constitutional treatment, little is to be expected, but change of climate is often of great benefit.

Topical treatment is of chief importance, even in health resorts. The choice of topical agents, and the proper methods of employing them, are carefully detailed.—*American Journal of the Medical Sciences*, March, 1889.

COLOR REACTIONS FOR FREE HYDROCHLORIC ACID IN THE GASTRIC CONTENTS.—SCHAEFFER (*Zeitsch. f. klin. Med.*, B. xv. 162, 1888) reviews the different color reactions for hydrochloric acid, the principal ones of these being, he says, 1, the aniline colors; 2, tropæolin; 3, Congo-red; 4, Mohr's reagent; 5, Uffelmann's test; 6, Günzburg's reagent. Congo-red he considers of no value, for, as Boas has shown, lactic acid will produce the same blueing as hydrochloric acid does. Uffelmann's carbolated-iron reaction is not at all delicate for the inorganic acid. Moreover, a yellow color is produced by a mixture of lactic and hydrochloric acids in certain proportions. For lactic acid the test is delicate, provided no glucose be present, with which it will produce the same tint; and glucose occurs in every stomach when the starches have been ingested.

Mohr's reagent is claimed to be reliable, and the author admits that it is so, in so far that no other substance but hydrochloric acid will give with it the peculiar coloration. His experiments have shown him, however, that it is far from delicate, and that it often fails to reveal the acid when other tests show its presence. Tropæolin is uninfluenced by any organic acid, and is very delicate, especially when used in the form of a tropæolin paper. It is decidedly to be preferred to Mohr's test, though it is not so sensitive as the methyl-violet and Günzburg's reactions.

Of the aniline colors, methyl-violet is the only one largely used, the others not having been found satisfactory. It is very delicate, but unfortunately not reliable, since other substances will produce the same change of color. Especially is it true that a 5 per cent. solution of lactic acid (a strength not so seldom found in the stomach) and of peptone will produce it. The changing from violet to blue may occur, therefore, when there is not a trace of hydrochloric acid present, but the absence of this change is a

positive proof of the absence of the acid. Günzburg's reagent is composed of 2 grams phloroglucin and 1 gram vanillin, dissolved in 30 ccm. alcohol. One or two drops of this are mixed with the same quantity of the fluid from the gastric contents, and heated gently in a shallow porcelain dish. At the edges of the fluid, as it is rolled back and forth, there develops a deep red color if organic acids are present. The author has made careful trials of this reagent, and finds that when the red color does not appear, the other reactions for hydrochloric acid are also absent. He also details his experiments in full which convinced him that the Gunzburg reaction was only absent when there was a complete absence of digestive power in the gastric secretion, depending on a diminution of the free hydrochloric acid. The reaction is not produced by any other body occurring in the gastric secretion than free hydrochloric acid, and is not interfered with by the presence of any other substance. The acid may be present and yet not answer to the test; it being combined with inorganic and organic bases. Thus, in carcinoma ventriculi, if hydrochloric acid be added to the gastric contents, some of it will disappear, having replaced the lactic acid in its combinations and set it free. In these cases, of course, the phloroglucin-vanillin test is negative; but it is always positive when any free hydrochloric acid *capable of digesting* is present. This last clause is, after all, the most important one, for whether any other form of the acid occurs is a matter of indifference from a clinical standpoint.

PREVENTION OF SUMMER DIARRHŒA IN CHILDREN.—DR. L. EMMET HOLT says (*Medical News*, Feb. 23, 1889): The treatment of follicular ulceration of the intestine is extremely unsatisfactory. I believe that the great majority of these cases are fatal. Certainly, I have never seen at autopsy in a child anything which resembled a cicatrized follicular ulcer. Successful treatment must be in the nature of prevention. Prevention must have regard to all the milder intestinal catarrhs.

Regarding neglected diarrhœas during dentition, so much has been said recently that it is scarcely necessary to enter here again a protest. There is to my mind no more reason why an intestinal catarrh should not be treated, and, if possible, cured during dentition than at any other time. The fact that a child with whooping-cough is extremely liable to bronchitis and pneumonia has never been given as a reason why these complications should not be treated promptly and energetically when they arise.

Is an intestinal catarrh ever salutary? This is questionable. A number of loose movements may be of advantage to expel undigested food or other irritating materials from the intestine, but

that a persistent intestinal catarrh, even if not severe, is an advantage to any child at any period remains to be proven. The medical profession should take strong ground against the prevalent popular opinion, that so long as the general health is not affected, an intestinal catarrh is not only of no importance, but may, during bronchitis or dentition, even be beneficial, and that to cure it might be injurious. It is in such cases as these that though amenable to proper treatment in the earlier stages, when allowed to run on, as they often are for weeks or even months, the foundation for grave and even fatal forms of diarrhoeal disease is often laid.

The prophylactic treatment involves then the early recognition and intelligent treatment of all the forms of dyspeptic catarrh: in other words, it means that we must secure proper digestion, and this depends chiefly upon proper feeding.

Our attention has been repeatedly called of late to the importance of seeing that our milk and other infant foods are pure and free from germs and putrefactive products. This is all important. Another danger which has not been often enough emphasized is overfeeding. During the past two years I have been trying to get at some exact data regarding the proper amount of food which an infant, who is artificially fed, should receive at the different periods. This has been studied, first, by measuring carefully at autopsies the capacity of the stomach; and, secondly, by weighing healthy infants who were nursed at proper intervals, before and after they were put to the breast. While I have not yet accumulated sufficient statistics for publication, still enough has been learned so far as to show that the figures given in most of our books are altogether too large, and that the vast majority of hand-fed infants are *very greatly overfed*. Difficulty and failure may result from this fact where every other condition for success has been attended to.

In conclusion I would emphasize the following points:

1. Children should not be overfed at any time, but especially not in summer.

2. At this season, also, every dyspeptic catarrh should be attended to: many of these are promptly curable by merely clearing out the intestine and then cutting down the quantity of food.

3. Should an intestinal catarrh, even a very mild one, continue for two or three weeks, one may be pretty certain that he has something more than a functional disorder to deal with.

4. Every mild catarrh should be looked upon as the possible precursor of a severe type of intestinal disease, either near or remote.

5. In the treatment of all diarrhoeal diseases it should be borne in mind that there is something more to be considered than the bacteria and the products of decomposition, viz., the anatomical changes.

MILROY'S MEDIO-TARSAL AMPUTATION.—At the meeting of the Surgical Section of the Medico-Chirurgical Society of Glasgow on January 25, DR. MILROY, of Kilwinning, exhibited a patient upon whom he had performed a new medio-tarsal amputation, and gave the following account:

On the evening of September 7, 1885, I was called to attend John Young, æt. 19, who had sustained a severe injury to the foot. I learned that a piece of iron about 2 tons in weight had fallen upon the back of his right foot. This weight had crushed and abused the tissues and bones so much, that amputation was considered absolutely necessary. The joint between the internal cuneiform and scaphoid was opened by the falling metal, and the cuboid was broken. The strong plantar tissues remained intact. On proceeding to amputate I left the scaphoid, disarticulated the cuboid, and then dissected a long flap from the sole of the foot. The dressings were first changed on the sixth day, when everything looked well. Progress from this time was uninterrupted. In less than a month the stump was perfectly healed. A short time afterwards he was allowed to go about on crutches, which he by-and-by threw aside, took for a short time to walking-sticks, and finally walked without any assistance. Nearly three and one-half years have elapsed since I performed this operation, and the cicatrix is no nearer the sole of the foot than it was six months after the operation. This young man can walk twenty miles at a stretch. He is working in a foundry where he requires to be on his feet for ten or twelve hours daily, still he complains of no pain in the stump. He walks with a slight spring, he has little or no halt, and wears an ordinary boot. I attribute these happy results to leaving the scaphoid bone. This operation may have been performed hundreds of times, for aught I know to the contrary. It is not, however, taught in our schools, or mentioned in our ordinary textbooks. In the Scotch schools we are told that if we cannot perform a Lisfranc, we should amputate at the ankle-joint by a Syme; at any rate we should keep clear of Chopart. I have in this instance kept clear of the much tabooed Chopart and of Syme also. This stump, to my mind, is superior to a Syme, and much superior to Chopart. There is a little arch formed by the scaphoid, astragalus, and os calcis. The weight of the body comes down almost on the keystone of this little arch. The scaphoid undoubtedly falls from the original position which it occupied in the ordinary and larger arch of the foot, but not so far as to bring the cicatrix under. I find that in such a case as this it falls about 25°, and the os calcis is raised the same. Now, had I made a Chopart instead, no arch would have been left, and the astragalus would fall through 35°, whilst the os calcis would be raised the same. This makes a very great difference, and would be cer-

tain to bring the cicatrix under; besides, the weight of the body no longer falls on the centre, but gives an advantage to the tendo Achillis of about 2 to 1. These facts, then, render this amputation far superior to Chopart's; but it is also superior to Syme's in this—the length of the limb is maintained; he has not that limp peculiar to a Syme; he does not require to wear anything but an ordinary boot; his base of support is greater; and he has, as I have already said, a slight spring. With these few remarks I wish to commend this operation to the consideration of you hospital surgeons, whose experience in operations amongst the tarsal bones is much greater than mine.—*Glasgow Medical Journal*, March, 1889.

FRACTURE OF TWELFTH RIB.—MR. JAMES CANTILE, of Hong Kong, reports two cases of this very rare injury.

Case 1.—On January 2, 1889, a man, the worse for drink, fell from his bed, a height of 3½ feet, on to a spittoon. The violence of the fall was such that the stoneware spittoon was broken in two. Not until the next day did the patient find inconvenience or pain. On the third day after the accident, he came under my observation, when a fracture of the left twelfth rib was evident. The rib was fractured 2 inches behind its tip; the distal portion of the bone was freely movable, and its broken end posteriorly overlapped the proximal portion slightly. Crepitus was evident both to touch and hearing, and to both the patient and myself. There were no complications. An encirclement of flannel gave sufficient support to render the patient more comfortable.

Case 2.—A patient came under my care, in the out-patient room, Charing Cross Hospital, in June, 1882, with fracture of both twelfth ribs. The history given was that of a fall backwards on to the edge of a plank, about 2 feet from the ground. The plank caught the patient across the loins, or rather exactly on the twelfth ribs. The fractures were palpable both to the bystanders and the patient, and the signs and symptoms coincided almost exactly with the fracture recorded under Case 1. No complications arose. The treatment was simply that of support by a flannel bandage, and the bones united with only a small knob of calius around the seat of fracture.

In the same clinic as Case 2 a case of fractured right eleventh rib was met with.—*British Medical Journal*, March 9, 1889.

THE CONTAGIOUSNESS OF PNEUMONIA.—In a long article on this subject NETTER reviews the epidemics of pneumonia which have been recorded, and adds a few other instances which have come within his own experience. His most important conclusions are as follows:

1. Pneumonia is a contagious disease of para-

sitic origin, and is transmissible either directly or by the intervention of a third person, or by inanimate objects, such as wearing apparel, etc.

2. The pneumococci are not destroyed by desiccation, and are diffusible through the air, but not to great distances, at most the interval between three hospital beds. They maintain their virulence for a period which has not yet been definitely determined, but probably never more than three years.

3. Contagion is possible through the entire course of the disease and even after recovery.

4. The period of incubation averages from five to seven days, but may vary between one and twenty.

5. Patients who have passed through a pneumonia are dangerous both to themselves and their neighbors, as living micrococci may be found in their saliva many years after. Thence in part the epidemic appearances of the disease in certain families during long periods, and also its frequent recurrence in certain individuals who have once survived it.

6. Rigid quarantine of the patients seems unnecessary, but other patients and healthy persons should not be brought into too intimate relations with them. The sick-room must be kept well ventilated and clean, the sputum disinfected, and the cocci lurking in the mouth destroyed so far as possible.—*Boston Med. and Surg. Journal*, February 21, 1889.

POSOLOGY OF SOME OF THE LATEST REMEDIES.—From a lengthy compilation in *Nouveau Remedes* for February, embracing a number of drugs which, while comparatively new, are no longer novelties to the pharmacist or physician, we select the following, giving in the first column the maximum single dose for an adult, and in the second the largest quantity that may be safely administered in the course of twenty-four hours:

Article	Maximum dose.	Amount that may be taken in a day.
Acid culebic	16.00 grs.	80 grs.
Acid sclerotinic	1.00 gr.	4 grs.
Adonidine	0.1 gr.	0.3 gr.
Amylene hydrate	80 minims.	
Anemonine	0.50 gr.	1.50 grs.
Apion	16.00 grs.	60.00 grs.
Apocodeine	0.50 gr.	1.50 grs.
Arbutine	16.00 grs.	60.00 grs.
Arseic bromide	0.16 gr.	
Aspidospermine muriate	0.05 gr.	0.10 gr.
Baptistine	0.05 gr.	1.50 grs.
Berberine sulphate	1.00 gr.	3.00 grs.
Boldogluin	60.00 grs.	240.00 grs.
Butyl chloral	16.00 grs.	60.00 grs.
Chlrysarobin	0.08 grs.	0.25 gr.
Convallamarine	0.10 gr.	4.00 grs.
Cotoine	0.50 gr.	2.00 grs.
Ethoxycaine	10.00 grs.	30.00 grs.
Ethyl bromide	20 minims.	1 dram.
Ethyl iodide	20 minims.	1 dram.
Euonymine	8.00 grs.	16.00 grs.
Homatropine	0.50 gr.	1.50 grs.
Iridine	3.00 grs.	10.00 grs.
Parcaine hydrochlorate	8.00 grs.	30.00 grs.
Parthenine	3.00 grs.	15.00 grs.
Picrotoxine	0.10 gr.	0.33 gr.
Silver cyanide	0.08 gr.	0.20 gr.
Silver iodide	0.33 gr.	
Solanine	1.50 grs.	5.00 grs.
Tribromide of allyl	8 minims.

SATURDAY, MARCH 30, 1889.

THE SENSIBILITY OF THE BLADDER.

In a communication on the "Sensibility of the Bladder in the Normal and Pathological State," made to the Académie des Sciences, on March 14, PROFESSOR GUYON said that in the normal state the sensibility of the bladder is manifested only when the desire to micturate is felt. To determine under what physiological conditions this desire is produced was the object of some researches undertaken by him. These researches have led to the following conclusions: 1. In the physiological state the desire to urinate is felt only under the influence of tension of the vesical walls. 2. Contraction of the vesical muscle precedes immediately the manifestation of this desire, which is perceived only when this contraction is carried to a certain degree. 3. The desire to micturate does not depend upon the action of a sort of elective sensibility, having a special centre in a determined point of the mucous membrane of the neck or body of the bladder; this sensation is situated in all parts of the organ.

In the normal bladder, says Guyon, sensation or contact is *nil* or obtuse. There is no sensibility to liquids that are unirritating; for solid bodies sensation is obtuse. Whatever be the position of the subject of the experiment, and whatever the movements of the body, the contact of the urine is never perceived. The same is true of warm water, boric acid solutions, and of weak solutions of nitrate of silver that do not cause immediate irritation. The subject of the experiment is never aware of the injection into the bladder of a

liquid at a temperature of about 18° C., but can distinguish between hot and cold fluids, and irritating fluids; the desire to urinate immediately succeeds this sensation. The interval separating the contact-sensation from the desire to urinate is proportional to the degree of the sensation. When a tepid liquid is injected to the degree of tension, the desire to urinate occurs. Supple instruments introduced into the bladder cause no sensation except in the urethra; nor do the extremities of bougies and sounds cause sensation in the bladder. Rigid instruments cause an obtuse sensation, which sometimes appears to be more pronounced near the neck, but does not cause desire to urinate. This desire is felt only secondarily, and is caused by repetition of the contact, sometimes by reason of its prolongation *in situ* or under stronger pressure—but especially on repetition, or by successive excitations. These experimental results are seen in practice. The normal bladder is indifferent or but slightly sensitive to contact. It invariably responds to tension by creating the desire to urinate. The bladder has not what may be called an anatomical capacity, but a physiological capacity—a capacity proportional to its sensibility—this capacity being variable, even in the normal state, and regulated by diverse conditions, physical or psychic. It is not the quantity of liquid that the surgeon introduces, but the reaction it determines that awakens the sensibility of the bladder. Anæsthesia shows the difference between contact-sensation and tension-sensation; under anæsthesia the first is abolished, but the latter remains.

It may be regarded as an established fact, says Guyon that tension is followed immediately by contraction, and this by the desire to urinate. A certain degree of tension may create the desire; but if the liquid be left in the bladder the desire ceases. A little more liquid may be injected now, when the desire again occurs, and again ceases. The surgeon may utilize this cessation of contraction to increase gradually the quantity of liquid introduced, if, as in a case of suprapubic cystotomy, he desires to distend the bladder.

It is a well-known that Küss and Duval are of the opinion that the desire to micturate is created by the flowing of a small quantity of urine into the deep portion of the urethra, and thier theory is generally accepted. Guyon claims that this portion of the urethra is insensible to the contact

of liquids. The first portion of this region, he says, is very sensitive; the second, or prostatic portion, is moderately sensitive to contact. Active pressure upon the membranous portion, repeated contacts, and faradization, when made from without inwards or *vice versa*, never create the desire to urinate; at the entrance to the bladder these manœuvres create the desire in some subjects. But this desire, always transient, becomes definite only when an instrument, carried into the bladder, is brought into repeated contact with the body of the organ. Hence, says Guyon, it is excitation of the urethral face and of the ring of the neck, not of its vesical face that causes a *transient* desire. Pressure *en masse* of the region of the neck produces the same effect. The neck of the bladder and the adjoining portion of the urethra have then, in the physiological state, less sensibility than the body of the bladder; and they are insensible to the contact of liquids.

In the pathological state the sensibility of the bladder is characterized by exalted sensitiveness to tension, and by more or less acuteness of sensibility to contact. Lively sensibility to contact, says Guyon, constitutes a pathological state. For diagnostic purposes it is very important to determine the degree and localizations of this morbid sensibility. The effects of distension in the physiological state are redoubled in the pathological state. The pain caused by exaggerated tension is hurtful to the bladder in the pathological state, and exercises a reflex action on the kidneys. In the pathological state, therefore, all tension and distension of the bladder should be carefully avoided. In painful states of the bladder Guyon has substituted instillations for injections, when it is necessary to use a moderately irritating liquid. He believes that in operations the object of which is to combat a grave painful state, section of the bladder itself is preferable to section of its neck, since he believes that in painful states of the bladder what has been supposed to be a contraction of the neck is really a contraction of the body of the organ.

FAITH-CURE IN THE COURTS.—At a recent trial of two "faith-cure apostles" in Sioux City, Iowa, for practicing medicine without a license, the Judge instructed the jury to find for the defendants, since under the laws of Iowa it was no crime for a person to pray for his afflicted neighbor.

THE UNION OF MEDICAL SCHOOL AND UNIVERSITY.

"Some of the advantages of the Union of Medical School and University" was the subject of an address delivered at Yale University last June, by Professor WILLIAM H. WELCH, of Johns Hopkins University. It is a hopeful and gratifying circumstance, says Dr. Welch, that within the last few years universities in this country and in England have shown an awakened and enlightened interest in the advancement of medical science and the promotion of higher medical education. Among the most notable evidences of this interest is the recent organization at the great universities of Cambridge and of Oxford of medical departments, not as detached schools, but as integral and coördinate parts of the universities. The vivifying influence of this intimate connection has been made manifest by zeal for research, equipment of laboratories, improved methods of instruction, and a more orderly and systematic scheme of study.

In Dr. Welch's opinion the union of the medical school and university will be a step in the direction of higher medical education. "The assumption by independent schools of medicine of the power of granting the doctor's degree, without any control from a university or from the State, is a main reason in this country for the lack of uniformity in medical education, for the enormous number of medical schools beyond all necessities of the community, for the ease with which medical degrees can be obtained, and for the consequent degradation in the significance and the value of the degree of doctor of medicine."

Of the 92 regular medical schools in the United States, 48 are medical departments of or affiliated with universities or academic colleges, and 44 are without such connection. Of the 13 Canadian schools, 12 have such connections, in all cases with universities, not colleges, and one is independent. Of the 48 American schools connected with academic schools, in about half the number of cases the academic connections are schools scarcely known beyond the boundaries of the States in which they are situated. In about the same number of cases, probably more, the medical colleges have such connection in name only, being in no way controlled by the regents of the universities or the trustees of the colleges. In one case a "university" has two separate and

distinct medical departments. The fertile American soil seems to be as productive of "universities" and "colleges" as of potatoes, and too often the greater attention is given to the proper planting and growth of the last-named.

While almost 50 per cent. of American medical schools have no academic connection, more than 90 per cent. of the Canadian schools have university connections; and the Canadian schools, as a class, rank with the less than half a dozen first-class American schools. Says Dr. Welch: "If we attempted to analyze the cause of German prominence in medical education, we should find that many causes combine to produce this result, but certainly not the least of these is the fact that medicine in Germany is taught only as a department in a university. Independent medical schools do not exist there. Something more than a feeling of piety for old forms has preserved the historic association of the medical with the other faculties. There is a conviction that the highest interests of medical education are best subserved by this association." Naturally we cannot expect to transfer the German university methods bodily to our soil, nor is such transference essential to a higher system of medical education. The school of physiology developed at Cambridge under Michael Foster is clearly traceable to academic influences, says Dr. Welch. It is of course possible that such results are attainable under favorable conditions, by independent medical schools; "but experience demonstrates that the highest development of medical education is attained to-day as it has been in the past, by the university system."

The mere formal connection of a medical school with a university is insufficient to bring about the results of which we speak. "There must be a union in spirit as well as in name. The influences of university methods and ideas must manifest themselves in the medical department, sympathetic relations must exist with other departments through the connecting link of all, the philosophical faculty, and the coöperation must be obtained of those physical and natural sciences, physics, chemistry, zoology, comparative anatomy, and botany, knowledge of which is essential to a complete medical education, and to scientific research in every branch of medicine."

What are the specific advantages that belong to the university system of medical education? The discussion of this question we must defer until a later date.

PROGRESS OF HIGHER GENERAL EDUCATION FOR MEDICAL MEN.

When, in 1859, the Chicago Medical College—Medical Department of the Northwestern University, was organized on the basis of three years of graded medical studies and a moderate standard of preliminary education for admission, it was comparatively rare to find, in the classes attending the medical colleges, especially in the newer States, regular graduates from universities, colleges or scientific schools.

The change that has taken place in this regard was well illustrated by an item in the public Commencement exercises of the above-named College on the 26th inst. Dr. Ephraim Ingals, one of the most enlightened and liberal members of the profession in this city not connected with any medical college, had instituted a prize of \$100, to be awarded the member of the graduating class who should attain the highest average standing in the three departments of literature, science, and medicine; the same to be determined by a competitive examination under the direction of a committee of the Faculty. A prize of \$50 was also offered by Dr. G. Wheeler Jones, of Danville, Ill., to the member of the class who should attain the next highest position as shown by the same examination. The Dean of the Faculty, in announcing the decision of the committee awarding these prizes and in presenting the graduating class to the President of the University, took occasion to remark that not only were all those who entered the prize contest graduates of literary colleges of high standing, but 18, or 40 per cent. of the whole graduating class, had been admitted to the medical college on diplomas from literary and scientific colleges, and of the remaining twenty-eight, all had pursued academic or collegiate studies from one to five years after leaving the ordinary public schools and before commencing medical studies. We hope the time will soon come when no person will be permitted to enter upon the study of medicine without presenting proof of a good literary and scientific education.

REGULATING THE SALE OF PROPRIETARY MEDICINES.

A bill has been introduced into the Ohio Legislature to prohibit the manufacture and sale of proprietary medicines in the State. Should the bill pass a fine of from \$500 to \$5,000 will be laid on

the manufacturer of such medicines, and their sale will be punished by a fine of from \$100 to \$300. In several other States than Ohio the question of the manufacture and sale of proprietary medicines is being agitated, and efforts being made to lessen the evils that undoubtedly arise from the indiscreet and indiscriminate use of the proprietary compounds that take up the larger part of the shelf-room in our drug-stores. Whether the bill before the Ohio Legislature is Constitutional or not we will not pretend to say. A less drastic measure, and one that, it appears, would meet with less opposition, would be the adoption of the French method of dealing with this question. There a "secret remedy" or proprietary medicine, before it is offered for sale, must be submitted to a Committee of the Académie de Médecine, which condemns the article, thus prohibiting its manufacture and sale, or approves of it and fixes the maximum price at which it may be sold. This Committee has the formula, and the method of preparation submitted to it, and the preparation is carefully investigated by an expert chemist. The New York *Commercial Advertiser* thinks that "if on every bottle of proprietary medicine offered for sale there should be a label giving a correct account of the substances contained in the compound, people would know what they were swallowing, and would swallow it at their own risk. The State has the right to require this, and the people could not quarrel with it." The State has undoubtedly the right to require this, but it is sheer nonsense to suppose that the people would then know what they were swallowing. And if people will swallow stuff in total ignorance of its composition, it is scarcely likely that what little knowledge they could gain from a label would exercise any influence.

EDITORIAL NOTES.

THE FORTIETH ANNUAL MEETING OF THE ASSOCIATION.—Both the preliminary programmes of many of the Sections already published and a recent letter from the Chairman of the Committee of Arrangements show that the preparations for the meeting at Newport are progressing in a most efficient and satisfactory manner. Not only the Rhode Island State Medical Society, but the profession in Boston and throughout the New Eng-

land States are affording gratifying indications of a warm interest in the coming meeting.

INDIANA STATE MEDICAL SOCIETY.—The Secretary of this Society, Dr. E. S. Elder, of Indianapolis, requests us to call special attention to the fact that the next annual meeting of that Society will be held commencing on *Wednesday*, May 1, 1889, a wrong date having been previously given.

DEATH AFTER VACCINATION.—In the *British Medical Journal* of March 9, 1889, the following case is cited: On September 24th the Public Vaccinator at Billesdon Union, near Leicester, vaccinated a little girl with humanized lymph in two places on the left arm. On the seventh day he visited her, finding the vaccine pustule well developed at each point, but broken and the lymph running down the arm, with an areola of redness around each, three-quarters of an inch in width. The next day the areola had assumed a more distinctly erysipelatous character. From this time it spread rapidly with much swelling; the hands and feet became densely œdematous; cellular abscesses formed near the elbow and in the back, and death ensued on November 19th following.

The origin of the vaccine lymph used was readily traced by Dr. Ballard, and found to have been free from contamination with the infection of erysipelas, but the house in which the child lived and its surroundings were in a very filthy and unsanitary condition. To these local conditions, Dr. Ballard attributed the unfortunate result. The responsibility for the death, was, therefore, properly attributed to the neglect of duty on the part of the local Sanitary Board.

DR. JEROME COCHRAN, State Health Officer of Alabama, has written an open letter to the Birmingham *Age-Herald* on the subject of yellow-fever disinfection, and in regard to the bitter and ungenerous manner in which he was denounced when he said that one of his patients in Decatur, last year had died of yellow fever. Dr. Cochran says: "It is argued that Decatur ought to be disinfected as a matter of policy, to quiet the apprehension of the people and adjacent States. It is precisely this spirit of apprehension, and the spirit of panic that follows in its train, and which is mischievous beyond power of words to give expression to, that stands in need of rebuke. Let

the people be taught again a great lesson. Let them learn that all the artificial means of disinfection that have so far been employed against yellow fever have proved to be comparative failures, while the great disinfectant which Nature sends to our aid—the beneficent frost of our winters—has never been known to fail." It is a matter of great doubt whether sanitarians will agree with him that artificial means of disinfection against yellow fever have proved to be comparative failures. If frost alone is to be depended upon there seems to be no hope for Cuba.

DR. KEI OKAMI, of Japan, and DR. SUSAN LA FLESCHÉ, of Nebraska, are among the recent graduates of the Woman's Medical College of Pennsylvania. The former is the first Japanese woman, and the latter the first Indian woman to study medicine. Dr. La Flesché was an Indian girl, who learned the English language at a reservation school, and completed her studies at the Indian School at Hampton, Va.

MEDICAL LEGISLATION.—Oregon and Montana Territory now have acts regulating the practice of medicine. The Oregon act, which is now a law, requires all practitioners to "possess a diploma of graduation, or a certificate from the board of medical examiners," according to the Albany (Oregon) *Herald*. In Montana, says the Bozeman *Chronicle*, the bill "requires the examination of all physicians in the Territory." We have no more explicit information than the above.

MEDICAL LEGISLATION IN TENNESSEE.—We learn that there is before the Legislature a bill to regulate the practice of medicine in the State of Tennessee. The bill is very stringent in its provisions, and traveling doctors or peddlers of drug nostrums or patent medicines are required by its terms to pay \$100 a month to the State. It provides for a State Board of Medical Examiners, who shall issue certificates or licenses to practice, either upon examination or upon proof that the applicant was a practicing physician prior to the passage of the act. These certificates shall be recorded in the office of the county court clerk. Practicing medicine without such a certificate shall subject the offender to a fine of \$100 for the first offense, and \$200 for each subsequent offense. The same penalty is attached to "any itinerant vendor of any drug, nostrum, ointment or applica-

tion of any kind intended for the treatment of disease or injury, or who may by writing, printing or other methods, profess to cure or treat disease or deformity by any drug, nostrum, manipulation or other expedient," who does not pay to the Board of Examiners \$100 a month for such privileges.

THE LATE OUTBREAK OF SMALL-POX IN MINNEAPOLIS, it appears, was very summarily and successfully dealt with by Health Officer Kilvington. As soon as a case was announced, a consultation was called to determine if the disease was small-pox. That being settled, the patient was removed to the quarantine hospital for treatment. The house where he lived was quarantined, and all the people directly exposed were confined in it. Dr. Kilvington's assistants then began to look up all people indirectly exposed, and vaccinated them. Quarantine houses had guards stationed about them, who allowed no one to go in or out during the season of quarantine. The quarantine people were vaccinated, and during the time until it could be determined whether the vaccination would take, they were supplied with food. When the vaccination took, the person under quarantine was bathed, given new clothing in place of the old, which was burned, and he was then discharged. When a house had been emptied of people under quarantine, the bedding and curtains were burned, sulphur burned in all the rooms, and the walls sprayed with corrosive sublimate. None of the inspectors or guards were allowed to enter any of the houses under quarantine, when there was danger, and the doctors that did the vaccinating saturated their clothing with the corrosive sublimate before and after entering a house where there had been small-pox. The clothing and bedding were either paid for at a reasonable price by the board of health, or were replaced by new articles. In one of the houses quarantined, there were 31 laboring men, who were inclined to object to the rules of quarantine. One escaped, but he was taken back when found, and a guard, with a rifle and instructions to shoot, should he attempt to escape, was put over him. Since January 13, 6,000 people have been vaccinated, and the schools, public and private, have been systematically visited, and unvaccinated children vaccinated.

FATAL RESULTS FROM SANTONIN.—The newspapers contain the report of two cases of death from santonin, given as a vermifuge to a little boy aged 3 and a girl aged 5 years. It appears that both deaths occurred within a few hours after the medicine was given. Santonin was administered also to a girl of 9 years, of the same family, and she was made dangerously ill.

REGISTRATION OF BIRTHS.—DR. C. A. LINDSEY, of New Haven, Secretary of the Connecticut State Board of Health, and Superintendent of Registration of Vital Statistics, has sent circulars to the physicians in the State calling attention to the law in regard to the prompt return of births, and to the fine provided for failure to make such returns. He has also sent the circular to every registrar in the State, with a request to make note of physicians neglecting to make returns. It is said that the law is disregarded to a disgraceful extent, and the State Board of Health proposes to make an effort hereafter to secure the monthly returns called for by the law. Every physician recognizing the importance of having birth statistics accurately recorded, should cheerfully and promptly comply with the law.

ASSOCIATION NEWS.

American Medical Association. Fortieth Annual Meeting.

To be held in Newport, R. I., June 25, 26, 27 and 28, 1889.

SECTION ON OPHTHALMOLOGY.

Papers have been positively promised by the following members:

Dr. Robert Tilley, Chicago, Ill.
 Dr. E. J. Gardiner, Chicago, Ill.
 Dr. S. S. Bishop, Chicago, Ill.
 Dr. F. C. Hotz, Chicago, Ill.
 Dr. H. Gifford, Omaha, Neb.
 Dr. J. F. Fulton, St. Paul, Minn.
 Dr. J. J. Chisolm, Baltimore, Md.
 Dr. J. L. Thompson, Indianapolis, Ind.
 Dr. A. E. Prince, Jacksonville, Ill.
 Dr. LeRoy Dibble, Kansas City, Mo.
 Dr. J. H. Thompson, Kansas City, Mo.
 Dr. A. R. Baker, Cleveland, Ohio.
 Dr. Dudley S. Reynolds, Louisville, Ky.
 Dr. Robert Sattler, Cincinnati, Ohio.
 Dr. C. M. Hobby, Iowa City, Iowa.
 Dr. J. W. Wright, Columbus, Ohio.
 Dr. F. B. Tiffany, Kansas City, Mo.

Dr. R. L. Thompson, St. Louis, Mo.
 Dr. P. D. Keyser, Philadelphia, Pa.
 Dr. W. G. Edwards, Nashville, Tenn.
 Dr. A. W. Calhoun, Atlanta, Ga.
 Dr. H. W. Williams, Boston, Mass.

Some of the above named authors have given in the titles of their respective papers. Those who have not should do so at once that the title of each paper may be published in connection with the name of its author.

Shall we have a short-hand reporter to take down all discussions? Or will members who discuss papers take the pains afterwards to write out what they may have said? Discussions ought to be published in connection with every paper, so that the different views entertained upon the subject of which it treats may be presented to the reader. Will *all* who are members of this Section please write the President or Secretary their wish on this point?

G. E. FROTHINGHAM, President,
 Ann Arbor, Mich.

G. C. SAVAGE, Secretary,
 Nashville, Tenn.

PRELIMINARY PROGRAMME OF THE SECTION ON MEDICAL JURISPRUDENCE.

All members desiring to contribute papers to this Section are requested to correspond with its officers.

First Day.—"History of Medical Jurisprudence," by Judge Amos G. Hull, of New York.

Second Day.—"Tests of Insanity," by H. N. Moyer, M.D., of Chicago.

"Monomania," by Clark Bell, Esq., of New York.

"Legal Decisions on Insanity"—Chairman's Address, by Jas. G. Kiernan, M.D., Chicago.

"Massachusetts Insanity Laws," by T. W. Fisher, M.D., of Boston.

"Illinois Insanity Laws," by Harriet C. B. Alexander, M.D., of Chicago.

Third Day.—"Legal Aspects of Inebriety," by T. L. Wright, M.D., of Bellefontaine, Ohio.

"Inebriate Criminals," by T. D. Crothers, M.D., of Hartford, Conn.

"Social Aspects of Alcoholism," by E. C. Spitzka, M.D., of New York.

Fourth Day.—"Spinal Concussion," by S. V. Clevenger, M.D., of Chicago.

JAS. G. KIERNAN, M.D., Chairman,
 Central Music Hall, Chicago.

S. C. EVANS, M.D., Sec'y., Baltimore, Md.

The names and addresses of Section Officers and other officers of the Association are printed on advertising page 25.

Special Attention is called to the following Rules of the Association:

It shall be the duty of every member of the Association who proposes to present a paper or

report to any one of the Sections, to forward either the paper, or a *title* indicative of its contents, and its *length*, to the Chairman of the Committee of Arrangements at least one month before the annual meeting at which the paper or report is to be read. It shall also be the duty of the Chairman and Secretary of each Section to communicate the same information to the Chairman of the Committee of Arrangements concerning such papers and reports as may come into their possession or knowledge for their respective Sections, the same length of time before the annual meeting. And the Committee of Arrangements shall determine the order of reading or presentation of all such papers, and announce the same in the form of a programme for the use of all members attending the annual meeting. Such programme shall also contain the rules specified in the By-laws and Ordinances concerning the consideration and disposal of all papers in the Sections.

No report or other paper shall be entitled to publication in the volume for the year in which it shall be presented to the Association, unless it be placed in the hands of the Committee of Publication on or before the first day of July. It must also be so prepared as to require no material alteration or addition at the hands of its author.

Every paper or address received by this Association, or by a Section, and ordered to be published, and all reports of Committees, and all plates or other means of illustration, shall be considered the exclusive property of the Association, and shall be published and sold for the exclusive benefit of the Association.

ORDINANCES.

Resolved, That the several Sections of this Association be requested, in the future, to refer no papers or reports to the Committee of Publication, except such as can be fairly classed under one of the three following heads, namely: 1. Such as may contain and establish *positively* new facts, modes of practice, or principles of real value. 2. Such as may contain the results of well-devised original experimental researches. 3. Such as present so complete a review of the facts on any particular subject as to enable the writer to deduce therefrom legitimate conclusions of importance.

Resolved, That the several Sections be requested, in the future, to refer all such papers as may be presented to them for examination by this Association, that contain matter of more or less value, and yet cannot be fairly ranked under either of the heads mentioned in the foregoing resolution, back to their authors with the recommendation that they be published in such regular medical periodicals as said authors may select, with the privilege of placing at the head of such papers, "Read to the Section of the

American Medical Association on the day of 18 .'' (Vide *Transactions*, vol. xvi, p. 40.)

Resolved, That no report or other paper shall be presented to this Association unless it be so prepared that it can be put at once into the hands of the Permanent Secretary, to be transmitted to the Committee of Publication. (Vide *Transactions*, vol xvii, p. 27.)

SOCIETY PROCEEDINGS.

Obstetrical Society of Philadelphia.

Stated Meeting, Thursday, February 7, 1889.

THEOPHILUS PARVIN, M.D., IN THE CHAIR.

DR. LONGAKER reported a case of

PLACENTA PRÆVIA.

The features of interest in this case are: *a.* Hæmorrhage at the seventh month in P. P. Lateralis. *b.* The patient was in a septic condition when first seen, a week after commencement of hæmorrhage. She was also very anæmic. *c.* Turning by the bi-polar method was at once done, and a living seven months' fœtus was born. *d.* The patient made an excellent recovery, and was sitting up in two weeks. *e.* The surface of the placenta showed traces of fatty degeneration. It contained a clot the size of a walnut and several days old. Placenta prævia occurred at her last confinement, three years ago, and she came near losing her life from hæmorrhage both before and during labor.

Case of Diseased Placenta, Anasarca of Fœtus and Hydræmnion.—Mrs. Z., æt. 28. Second ipara at seventh month of pregnancy. Her first child lived but a short time. The amniotic fluid was in excess, and child and placenta weighed 5³/₄ pounds. About one-third of the placenta was the seat of a well-marked change. There are foci, cheesy in the centre, gradually passing into apparently healthy tissue. These were more or less continued, involving a V-shaped segment. The abdomen of the child was so distended as to cause a slight obstacle to its delivery. Œdema of the extremities was slight. Both the pleura and pericardium were distended. The greater part of both lungs was solid, and on section a purulent fluid exuded from the cut surface. The child's extremities were rigid and flexed. It had been dead but a short time. Careful auscultation had, however, failed to detect fœtal heart sounds during labor.

DR. HOFFMAN reported a case of

PYOSALPINX.

I shall go into the history of this case with rather more attention to detail than would be

warranted, were it not for some features of previous history and treatment, which render it in some respects more than ordinarily instructive.

Mrs. G., æt. 28, came to me for examination in August, 1888. Her history at the time was unsatisfactory, giving simply record of a discharge for a long while, and great pelvic pain, especially on the right side. A miscarriage was admitted. Examination showed a painful mass, bound down to the right cornu uteri, so tender that exact mapping out was impossible. I doubt, however, whether even under an anæsthetic an accurate diagnosis could have been made of the condition as revealed by operation, owing to the involvement of intestine. Intestinal adhesions always increase the size of ovarian and tubal tumor, rendering the decision of absolute extent impossible. The left side also was evidently involved, but was not so painful as the right. I made no great effort to determine the extent or nature of this involvement, inasmuch as her condition was evidently one for operation, as I told her, saying at the same time that treatment would be entirely useless. She left my office crying and I saw no more of her until two days before operation, December 18, 1888. I then ascertained that after seeing me she had gone to four other physicians, one whose diagnosis was uterine displacement, and whose treatment was the introduction of a pessary, strangely enough with the result of apparent relief. She then visited the clinic of the Woman's Hospital, and was comforted with the assurance that there was nothing the matter with her and that she should go home and have a baby. She received like advice at the University. An up-town specialist, into whose hospital she afterwards went, with the intention of operation "for a ruptured blood-vessel," the then diagnosis, told her there was no necessity for operation, advising her that she was wise not to have submitted to it at my hands, promising her at the same time that she should have a baby, and to promote this end, the uterus was curetted. Time wearing on, she again visited her last adviser, who now made the diagnosis of a ruptured blood-vessel, and advised operation for its "tying." At this juncture she again fell into my hands, much reduced from excessive hæmorrhage for three weeks. I did not examine her, but urged immediate operation, to which she consented. Two days later abdominal section was done. Assisted by Dr. J. Price, the right side was first explored and the ovary and tube found everywhere densely adherent. Enucleation was accomplished with much difficulty, and when attempt was made to apply the ligature, the tissues were found so rotten that the blood-vessels alone withstood the tension of the silk. The right cornu uteri was so involved that it was simply a mass of abscess tissue, and had to be curetted in order to free it from the necrosed portions. The bleeding was now so profuse that

the application of a new ligature was necessary. The second ligature was wholly about uterine tissue. The left side was then examined and found even more extensively involved than the right, but without the presence of pus. The adhesions were more dense, but the tissues not being necrosed, there was no difficulty in obtaining a good pedicle. The involvement of the intestines was so great that I fully expected a fæcal fistula to result, in spite of careful suturing. The right tube contained pure pus. A drainage-tube was introduced and kept in the incision a little more than a week. The only complication was severe inflammation of the bladder, and phlebitis of left internal saphenous vein. The patient is at present moving about her room.

The history of her trouble, since obtained, is interesting. She was married at 16. Six weeks after her marriage her husband deserted her. Her baby lived seven months, going blind some time before its death, having sores and becoming very emaciated. At this time she began to have a bad discharge, which inflamed her private parts, which were also much swollen. Had great pain on urination. She did not have intercourse for twelve months after the birth of her baby. She then contracted an alliance with another man, and afterwards within three years had two miscarriages, and a still birth at eight months. Her hair has fallen out, but aside from this she has had no other sign of syphilis. The question here arises, what was the origin of the pelvic trouble? Was it gonorrhœa, syphilis, abortion, or the after-effects of labor? That there are chances for believing, according to the various aspects of the case, that perhaps one, then the other of all these agencies, entered into the causation of the disease, will, I believe, be not disputed. Whether or not it is so conceded, matters very little, however, so far as this case is concerned. That all these factors may bring all the various forms of pelvic disease cannot be rationally disputed. That we can dogmatically affirm that any pelvic lesion is brought about by any one of these causes, with the exception of gonorrhœa, as proved by the presence of the gonococcus, is not to be for a moment entertained. The fact is, we can have the symptoms of pyosalpinx simulated in all its essentials by an entirely different condition, to-wit: tubercular disease of the appendages. To consider the relative frequency of each of these factors in the production of pelvic disease, it is not my purpose, but it requires more than the dogmatic assertion of any operator to prove that this, that or the other cause is always at the bottom of the lesion. But while the etiology of the trouble may be obscure, in a well-defined lesion like the one under observation, the diagnosis ought, in most instances, to be made, or if it cannot, the question concerning it should be gone over, chances for error discussed, and once for all have

it confessed that the subject of pus-tubes and ovaries is not too hackneyed for consideration before a Society such as this. We read of the infallible bi-manual examination, which is able to pick up a Fallopian tube or distinguish varicose veins in the broad ligament, and then suddenly are confronted by failures such as I have here recorded. The fact stands out that the diagnosis insisted upon, by the men who are accustomed to "claim everything," is a myth, and as Mr. Tait says, fit only for library papers. It is incredible that the diagnostician who can recognize, map out and differentiate the Fallopian tubes, should fail to recognize a mass the size of a small fist. Let us by all means have diagnosis, but let it be *diagnosis*, not myth. In this case the diagnosis, promises and treatment well nigh lost the woman her life. She wanted a baby and she was promised one. She nursed the delusion for three months. Promises may hold patients, they do not work cures, nor save reputable medicine the slur and suspicion of quackery. I believe in the present case that the curetting was directly responsible for the involvement of the uterine tissues. In the presence of tubal disease there is no excuse or palliation for the use of the curette. I believe that the so-called operation of "dilating and scraping" is responsible for much tubal and ovarian trouble that would otherwise remain quiescent. I have now a case under observation where this procedure was resorted to, without relief; then electricity was tried, and to-day the patient is worse than ever, with operation her only relief.

DR. HORATIO R. BIGELOW read, through the Secretary, a paper on

APOSTOLI'S PLACE IN GYNECOLOGY.

After some complimentary remarks on Apostoli himself Dr. Bigelow went on to discuss the armamentarium necessary for carrying out the electrical treatment. He thought it necessary to have a galvanic battery, a faradic battery, a collector, a galvanometer, intra-uterine electrodes for both currents, and one for carrying both the positive and negative of the induced current within the uterus; bulbous charcoal-pointed electrodes of various sizes for galvano-caustic applications, intra-uterine platinum electrodes, and large bulbous vaginal and rectal electrodes. The belly-plate could be made of potter's clay, in which the metal plate could be buried, or better is the plate devised by Martin, of Chicago. A good galvanic battery should have a slight chemical action and great constancy. The Léclanché cells or those of Daniell he thought the best. With 36 Léclanché cells, without a rheostat, a strength of from 300 to 350 milliamperes can be gotten. He thought that the collector was invaluable, and that to measure the dosage exactly was an absolute prerequisite of success. The best galvanometer was

that made by Gaiffe. The best faradic battery that of Gaiffe, with a chloride of silver pill, and the induced currents of high tension from the long thin wire was the one to be generally used within the uterus.

"The induced current penetrates the tissue profoundly by reason of its high tension, but, contrary to physical laws, the continuous current of low tension has a longer and more profound action. We have proved the diffusion of the electric currents, and that the galvanic current propels itself through organic tissues, its influence being felt at remote points, the current *never remains limited between the two poles*" (Omninus). "If we now consider the difference that exists between continuous and induced currents during their constant passage we find that it is not difficult to distinguish between them, as the line of demarcation is clear. The induced current acts for an exceedingly short time during its passage. It produces at each instant of passage a greater or less excitation and causes molecular shock. The induced current acts mechanically as an excitant, but the continuous current penetrates more gradually the tissues, but more profoundly, acting chemically in such a way as to produce molecular orientation and chemical combination" (Omninus). The induced current traversing the liquid, semi-liquid, or solid substances that go to form the human body, produces no chemical action whatever, simply a mechanical molecular disturbance. The continuous current, however, not only produces its chemical action at the poles, but this molecular disintegration and orientation is propagated throughout the zone between the poles. Just what the galvano-caustic action is that dissipates a tumor is not yet known—whether it coagulates the albuminoids or creates interstitial inflammation, he does not know. *It does reduce the tumor* and it remains for us to find out the *why?* He believed that time would demonstrate a change of *cell life* in addition to the purely chemical action, which takes place around the poles. In Apostoli's clinic the induced current is not often used. It has a wondrous effect, however, upon the ovarian pain in hysterical women. Dr. B. has now seen 20 cases of this kind and every woman received immediate relief after a séance of ten to fifteen minutes. He has seen a large number of bleeding fibroids, but has, as yet, to see one that failed to respond immediately to the continuous current, the positive pole being within the uterus. Apostoli often carries the current up to 350 milliamperes without any discomfort to the patient. It is most important that every part of the lining membrane of the uterus should be treated, and every hæmorrhage, no matter how severe it may be will resist. Dr. B. affirmed that the treatment would very appreciably diminish the size of fibroids and at times entirely dissipate them. He quoted cases to prove this point. Punctures were

made into the tumors to the depth of from 1-3 centimetres, with a lance-pointed steel needle, the galvano-negative caustic being used, usually. Everything was religiously clean and antiseptic. None of the patients had any bad symptoms. He affirms that Apostoli's method arrests hæmorrhage, diminishes size, relieves pain and improves nutrition, without endangering life, better and more surely than any other method, and asks, why then resort to Tait's operation of excision of the appendages? The catarrhal forms of salpingitis yield kindly to the simple action of the continuous current, one pole in the uterus. Dr. B. is not yet ready to offer any decided opinion in regard to pyo-salpingitis. He however cited several cases where negative punctures of the tube relieved or cured the cases. In metritis the galvanic or faradic current should be used as one or the other agrees with the patient. Apostoli says that "this treatment applied according to his double or bi-polar method is an excellent and sometimes sovereign remedy in certain cases (recent subinvolution, chronic metritis in its first stage), inefficacious or at least very insufficient in others (such as chronic metritis in its latter stages), and endometritis in any form." In endometritis the continuous current and the positive pole within the uterus are used. He cited some cases of fungoid endo-metritis which had been cured. Dr. Apostoli faradized every woman, even when under an acute attack, who was suffering from peri-uterine inflammations, observing certain rules which he has laid down. In the sub-acute stage he uses, first, bi-uterine faradization, with a current of tension when the inflammation begins to give way he used the intra-uterine continuous current, beginning first with the positive pole and following with the negative as as soon as he is sure the patient can bear it. In the chronic stage use the continuous current and galvano-puncture (negative), making the puncture in the diseased part itself. In old cases of perimetritis, with much tenderness around the utero-sacral ligaments, much relief may be obtained by the vaginal electrode in the posterior fornix, while the negative pole is in the abdomen, using the induced current of high tension.

DR. JOSEPH PRICE reported

A YEAR'S WORK IN A MATERNITY HOSPITAL.

In making this report I desire briefly to call attention to the amount of work done, the routine treatment of patients, and a few alterations which have taken place in the building. During the year 1888 there were 184 deliveries in the Retreat. Of these patients 69 were primiparas. There were 186 children born, including two sets of twins, 9 of these infants were stillborn, 102 were males, 84 were females. There were 13 forceps deliveries. Labor was induced in 2 cases in the eighth month. In 1 case a contracted pelvis and

in one the presence of a large uterine tumor. There have been no deaths of mothers in the Retreat for a period of nearly five years, furnishing a series of 540 deliveries without a death, the last death being from puerperal convulsions in a patient suffering from chronic Bright's disease, and who had had convulsions in five previous labors. Since this death there has not been a case of puerperal septicæmia in the institution. The great success attending the work of this Maternity is due to the strict enforcement of the law of cleanliness. Everything and everybody in the house is clean and jealously kept so. This system was enforced by Dr. Goodell, and has been carried out on the lines laid down by him. The routine treatment of patients is as follows: the patient on entering the house is given a hot soap bath, dressed in clean underclothing, and given a clean bed in the waiting ward. If necessary, a laxative is given and the bowels kept soluble during her waiting period. Thereafter, until her confinement, she is obliged to take at least two hot soap baths per week and to wear clean clothes. She is allowed to do such light work about the house as the physician may deem advisable, and is encouraged to take as much open-air exercise as circumstances will permit. Every effort is made by the officers and employes of the institution to make it as cheerful and homelike as possible. When ready for the delivery room the patient is again given a hot soap bath and an enema and a vaginal injection of 1 to 2000 bichloride of mercury solution. She is clothed in a clean night-robe and drawers and placed upon a new clean delivery bed. Scrupulous cleanliness is observed in all manipulations of the patient, and after delivery a second vaginal injection is given, and a vaginal suppository of iodoform is introduced. The patient's person is carefully cleaned and all soiled clothing removed, the binder applied, a clean set of night clothes put on and the patient placed in a new clean bed in the ward. All of the soiled articles are immediately removed from the delivery room and a new bed made up for the next patient. The patients in the ward are carefully observed by the nurses, but no unnecessary handling or interference indulged in. The patients remain in the ward until they are able to be up, when they are removed to the convalescent ward. As the ward is emptied, the beds are burned and all the bedding most carefully cleansed. No soiled linen (as draw-sheets, diapers, napkins or other articles of clothing) is allowed to remain in the ward, but when soiled is immediately placed in a covered receptacle and removed from the ward and building. No sponges, wash-rags or absorbent cotton are used in the house. Corrosive jute supplies the place of these articles, being clean, soft, remarkably absorbent and cheap; it is destroyed immediately after use. The pads used to absorb

the lochia are also composed of jute and are likewise destroyed after use. The beds in the wards are of new straw. All discharges from the delivery room are immediately burned. All bedding soiled beyond cleansing or contaminated by purulent or specific discharges is likewise burned. In short, every effort is made to keep the house perfectly pure and sweet. The arrangement of the house permits of rotation in the use of the wards, so that a ward, once emptied, is not again used until three others have been filled. In the meantime it is most carefully and scrupulously cleaned and thrown open to the atmosphere. A similar system is pursued in the convalescent wards and delivery room. A few alterations in the building have very markedly increased the effectiveness of the institution and the comfort of its inmates. In the first place, the bath-room and water-closets have been removed from the building proper and placed in the towers in the rear. The plumbing is as near perfect as modern sanitary science can make it. The verandas have been enclosed in glass, forming large, light, airy corridors about the rear of the building, and furnishing a distinct circulating atmosphere between the house proper and the wards and the water-closets. The ventilation of the entire building is simply perfect. The capacity of the house at present is about fifty patients per month, and, when a few contemplated changes are made, the capacity will be doubled and the institution rendered as nearly an ideal maternity hospital as is practicable.

DR. WM. GOODELL said it had always been a matter of great regret to him that he did not adopt this system a year or a year and a half before he did. He supposed it was partly due to the conservatism of old age and partly to a series of some forty deaths from bichl. poisoning he had collected. Tarnier's reports of the results following the use of this agent so impressed him, that he was led to make the change. Before he adopted the system which has just been detailed by Dr. Price, he had once as many as five deaths in about 150 cases, four of these due to septicæmia. Latterly hardly a year would elapse without the occurrence of one or two deaths. When he first started everything about the institution was new and clean, and for several years he had the best record of any maternity hospital in the world. After the building and articles had become old, deaths began to occur. He tried carbolic acid, but it proved of little value. After beginning the use of corrosive sublimate injections, iodoform suppositories and antiseptic pads, he did not have a death from septicæmia. The only death was one from Bright's disease of the kidneys. During this time he had been consulted perhaps a dozen times in the course of a year to see women dying from puerperal septicæmia. He thought that, in private practice, it would not be needful

to follow out so strictly the details of the method as it is practiced at the Preston Retreat. For instance, the antiseptic pad and the iodoform suppositories might be done away with. He believed, however, that every practitioner should syringe out the vagina both before the birth of the child and after complete delivery, with a bichloride solution of 1-2,000. The hands should also be disinfected. He was called in consultation by a physician in the country who had had four or five deaths from sepsis in a short time. I found he been treating a case of phlegmonous erysipelas. He knew of another physician who had lost, he thought, seven cases—certainly five, from dressing a sloughing case of erysipelas. Antiseptic measures would probably have saved all these cases.

DR. HENRY LEAMAN would call the attention of those who have the opportunity of observing the physiological processes of labor to one point, viz.: presentation. It is very difficult to accurately determine the presentation, particularly of the face, brow, and posterior presentations. These observations should be verified by examination of the abdomen previous to labor and the location of the foetal heart sounds. They should also be confirmed by observation of the position of the head in the act of delivery. A mistake is readily made in posterior presentation. Posterior presentations are, he thinks, more common than we are in the habit of considering them. His object in speaking was to say that every case of labor was a case for the minutest observation. There was another point which he thought should be observed, that was the hour of the day at which labor occurs. There is, he thought, probably some connection between arterial pressure and the time of delivery. In recording the hour there would be an allowance to be observed in cases where the forceps were used. There was another point not mentioned, and that was the position of the succedaneum and its extent. These have to do with the natural process of labor and aid in determining the presentation.

DR. J. PRICE said he was as anxious about a labor as he was about a section, when he read reports of maternity hospitals with a mortality of from 2 to 27 per cent. This troubled him not a little now that he controlled a large maternity hospital, one in which Dr. Goodell had left a record of 275 cases without a death. He sees a labor case as frequently as he does a drainage after abdominal section. When this hospital was new, Dr. Goodell had a run of 250 cases without a death from any cause. This was the longest run of any institution at that time. After this deaths began to occur. Later he adopted the gospel of cleanliness, and with what results he has just told you; the results are now precisely the same as he left them. In regard to Dr. Hirst's question as to whether the same results might not be obtained by simpler methods, Dr. Price said

that they did not differ much in regard to the use of solutions and that portion of the treatment. The toilet of the house was perhaps just as systematically carried out at the Philadelphia Hospital as at other institutions. The pad which he had shown would hold a pint of fluid. It saved an immense amount of laundry work. It was now coming into use as a menstrual pad and was very convenient for ladies traveling. In private practice the mortality was greater among the rich than the poor. Among the poor he had had 700 deliveries without a death. He thought the difference was in the water-closets which the better classes had in their houses. The mortality throughout the country was large. In a small town in Ohio, with a high elevation and beautifully located, he had recently known of two deaths from septicaemia. Last summer he had been called to see puerperal cases nine times, and all died.

Gynæcological Society of Boston.

Annual Meeting, Thursday, January 10, 1889.

THE PRESIDENT, HORACE C. WHITE, M.D.,
IN THE CHAIR.

Dr. John H. Mackie, of New Bedford, was elected to Corresponding Membership.

PATHOLOGICAL SPECIMENS.

DR. A. L. NORRIS presented a *tumor of the breast*, which he had removed from a woman, æt. 53 years. It had been three months forming, was extra-mammary, and of the size of a goose egg. Blood had oozed from the nipple, which contained broken-down blood-cells and cancer-cells. The axillary glands were not involved. The entire mass was removed. It was a schirrus which Dr. N. had never before seen as extra-mammary. The entire gland was also removed.

DR. F. L. BURT reported a case of *fibroid complicated with hydro-salpinx*, and exhibited the specimens. The patient had been under treatment about a year. There had been troublesome hæmorrhages. Laparotomy was performed for the removal of the diseased tube and ovary, and for hastening the menopause. Glass drainage tubes were used. The patient made a good recovery.

DR. E. C. KELLER reported a case which had been under observation since last August. The patient had been treated for localized peritonitis. Severe pain at first was one of the leading features of the case. On the 27th of December the patient had a severe attack of flooding, was blanched and fainted. On January 3, laparotomy was performed. There was a cyst near the left broad ligament. The ovary of that side was filled with blood. The hæmorrhage was from the Fallopian tube. The case appeared to be a

hæmato-salpinx. In reply to inquiry from Dr. Stevens, whether the tube was ruptured, Dr. Keller said the tube was not ruptured, and that the hæmorrhage must have come from a ruptured vessel. The original clot where the hæmorrhage first began was plainly visible in the specimen as exhibited by Dr. Keller.

DR. HENRY O. MARCY exhibited a *dermoid cyst, weighing about ten pounds*, which he had removed from a woman about 35 years old; was assisted in the operation by Drs. Nelson and Cole. The abdomen was nearly the usual size at term. She had been under the care of two physicians who were so assured of pregnancy, that she had prepared the wardrobe for the expected infant. The diagnosis was doubtful, but the uterus, about three inches deep, could be differentiated from the tumor which was semi-solid. The tumor was removed with extreme difficulty, as it was more solid than fluid. The broad ligament was sewed off with the double stitch. The left tube was dilated with fluid to the size of a large sausage and the ovary was diseased. They were removed. The dermoid tumor was full of bony points, and had many cysts filled with colloid material. Patient made a good recovery.

Dr. Marcy also showed the *ovaries and tubes* which he had removed from a woman, æt. 30 years. She was very weak and hysterical, suffered great pain at her menses, and had been an invalid for six or seven years. The pain at the menses was such that she took morphine subcutaneously every two hours until a grain had been used.

Dr. Marcy further exhibited an *extra-mammary tumor of the left breast*, which he had removed from a widow, æt. 43, who had never been pregnant. There was no history of injury. It began a year ago as a small nodule to the left of the nipple. It is now double-fist size. There was no glandular enlargement in the axilla. Histologically, the tumor is a myxoma, the first case he had ever seen. It was behind the gland and was firmly attached to the pectoral muscle.

EXHIBITION OF NEW INSTRUMENTS.

DR. GEORGE W. JONES exhibited an *Improved Gynæcic Harness for the Retention of the Patient during Gynæcic or Rectal Operations*. Doubtless it will be conceded by most of you, who have had experience in these operations, that the most convenient position in which to place the patient for operation, is the dorsal; for in that position, the uterus and other organs are in the most normal position. Under these circumstances, however, you have also realized that the legs and feet of the patient must be taken care of and held out of the way, in order that the operator may do with facility and comfort whatever his hands find to do. To accomplish this and attend to the ether, at least three or four competent assistants are required; and such an array of heartless doctors

before a timid patient, is many times trying to her nerves, and sometimes may be detrimental to the successful performance of a simple operation. In order to be useful, an appliance must be simple at the same time that it supplies requisite qualifications. This harness fills the requirements mentioned. It consists of the following parts, viz., a yoke, made by a piece of brass tubing twelve inches long, into each end of which another piece twelve inches long and of smaller size, slides perfectly. These two smaller pieces are curved in the proper manner for one-half their length, and a hook is attached to the curved end. As these pieces slide into the larger tube, they are held by thumb-screws at any required distance. The rest of the apparatus consists of a stout piece of webbing with a ring attached to each end, to go around the neck of the patient. To this webbing are fastened two short pieces, which go under the axilla and fasten to the rings in the ends of the neckpiece, thus preventing it from slipping up. Through each of these rings also, a narrower piece of webbing slides freely, with a ring at each end to fasten to the yoke before described. In using this harness, the patient being in the dorsal position, the webbing should be adjusted to the shoulders, then with the legs flexed upon the abdomen, the yoke can be placed under the knees, and attached to the rings at each end of the tapes. These tapes may be shortened or lengthened at will while in use, or they can be removed entirely in an instant if necessary in case of accident. The whole apparatus can be boiled or rendered aseptic in any manner most desirable. It can be taken apart in a moment and carried in the hand-bag with little additional weight or trouble.

I have also what I have styled the *Aseptic Universal Needle Holder*. It is eight and one-half inches long, with a smooth symmetrical handle, a unique spring-catch and a button joint. One of the special features of this instrument is the formation of the jaws. The upper half or blade is rounded on the inner or usually flat side, and it contains a groove of sufficient size to hold firmly a Hagedorn or any other needle, curved or straight. It is also of extra length, an advantage readily appreciated by any one, who has attempted to suture high up in the vagina with the ordinary short holder. Its symmetry and simplicity, and the fact that it can be taken apart and cleaned in the most thorough manner in a moment, render it the most aseptic needle holder made, and a valuable addition to the aseptic gynaecological or other instrument case.

The next instrument is an *Improved Dilator for Rapid Dilatation of the Cervix Uteri*. Although, as you see, it is very much like the "Wiley Dilator," yet it has some advantages over that instrument. One of the handles is curved, so

that the hand of the operator does not obstruct the view of the part operated upon. Another improvement, and the principal one, lies in the joint, which is movable or a sort of toggle joint, which can be changed at pleasure, and extreme dilatation obtained if desirable. Moreover, if greater dilatation is desired at the external os, it may be obtained without too great tension being made on the internal os, and *vice versa*. The instrument may be taken apart in a moment and rendered perfectly aseptic. Codman and Shurtleff will supply any of these instruments.

THE PRESIDENT, DR. HORACE C. WHITE, then delivered

THE ANNUAL ADDRESS,

which was listened to with marked attention and interest by the Society. He said: I will occupy but little of your valuable time in presenting a few rambling thoughts and suggestions, with regard to our Society.

In our eager search for scientific facts, and in the busy whirl of the routine of daily professional duties, time passes so rapidly that it is well sometimes to stop and look over what has been accomplished, and changes have taken and are taking place.

The Gynaecological Society of Boston has just completed its second decade. Twenty years ago, when this society, which claims to be a pioneer in its department, was formed, it would have been an easy task to have reviewed a year's progress, and perhaps that which had been written strictly upon this department of Medical Science, then in its swaddling clothes, in a single address, and not have exhausted the time allotted. A few ovariologists, whose daring shocked their more conservative brethren, and whose percentage of death-rate would hardly have made their patients in haste to accept their services, constituted a large part of the abdominal surgery of that day. These were the advanced guard of the serried columns who now assault the well recognized foe, from every point of attack, and with numberless implements of warfare.

This Society was not only a pioneer, but it has done its share in causing Gynaecology to be recognized as an honorable science, and to reclaim it from opprobrium, and to place it upon a respected equality with other departments of medical science. Its founders were able, earnest, and conscientious men, who struggled with difficulties, which we of to-day, can hardly realize, and to them great credit is due for the honorable standing of the Society.

With familiarity in the use of anæsthetics and with the more recent discoveries which have given birth to antiseptic surgery, great advance has been made. The field has been continually broadening; like the progressive series it shows wonderful increase, until now it would seem

nearly impossible to bring anything like a complete review of a year's progress into a single address. If we should select a single operation and attempt to review all that has been said, written and done, we should exhaust our time long before we exhausted our subject. If a new principle of treatment or theory of disease were selected, we should still have the same almost unlimited mass to select from for discussion. Materials and methods of their use, as for instance sutures, needles and dressings, would be a fruitful source to draw from.

The use of electricity in its various forms, with its varied and ingeniously constructed batteries, its application as a remedial agent, both in medicine and surgery, its use to strengthen feeble vitality or to destroy diseased tissue, to promote growth or to retard overgrowth, to restore to life those who are apparently dead, or to take the life of those who are condemned to death, not mentioning its use as an accessory or convenience, such as lighting our houses and streets, ringing our door-bell whether we are awake or asleep, and summoning us, over the wire, by day or by night, with many other uses, this magical power, yet in its infancy, so far as its scientific and proper use is concerned, may, by the efforts which are being made to measure its power and estimate the resistance which it is capable of overcoming, be brought within the range of dosable remedies, and be a very important factor in the treatment of human maladies. A course of lectures might be written on this subject.

We recognize the fact that knowledge is increasing, that science is developing new truths, but what would he say now, who so long ago said "of making books there is no end?" If all that was written was truth unmingled with error, if there was no dross with the precious metal, we might soon expect the millennium of scientific knowledge, judging from the amount written; but while we believe that scientific knowledge is increasing, we cannot close our eyes to the fact that much that is advanced for truth will not stand the actual test. The growth of scientific knowledge like the growth of the body, is a slow process, costing great destruction of the old to bring in the new. Now if a review of a year's progress requires the discrimination between truth and error, a summarizing of what has been taught, that will stand the test of time and experience, then the task would present such a mountain of difficulties and impossibilities that no one would dare attempt to surmount them. It would be much easier and perhaps as profitable to follow the example of Artemas Ward, in his lecture on "The Babes in the Woods;" spend the whole of the time in telling why he did not lecture on this, that and the other subjects, and conclude his lecture by saying he had, therefore, made up his mind to lecture on "The Babes in the Woods."

During the past year we have held ten meetings, with an attendance varying from 25 to 75 per cent. of our membership. When we consider the imperative demands upon the time of a physician, which cannot be regulated by his wishes, and also the fact that two-thirds of our members reside outside of the city, this is not a bad record. We have had at nearly every meeting valuable papers and much profitable discussion. We have also had a large number of interesting and instructive pathological specimens exhibited, with detailed reports of cases and operations. Our by-laws have been revised and printed again with a list of the active members.

In September Dr. H. J. Harriman, who had served the Society as its Secretary so efficiently and faithfully during the past four years, was obliged to resign his office on account of ill health. The Society accepted his resignation with regret. In this connection, allow me to say that our Society records are a feature of which we may be justly proud. From the beginning it has been very fortunate in the selection of its Secretaries. This very important office, which combines the duties of Secretary and reporter, has been filled from the first by men who would be an honor to any medical society, as will be shown by inspection of its records. To Dr. Field, who so long and acceptably filled the office, the Society will be under perpetual obligation for having all the records neatly copied into suitable books up to the expiration of his term of service. I would recommend that this work be continued up to date.

Allow me further to recommend a plan suggested to me by the Secretary, which I think will do much toward keeping up the interest in the meetings, viz.: to have our reports promptly and regularly furnished to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION for publication, and to have a sufficient number of "reprints" ordered by the Society so that each member may have a copy. By keeping these and getting them bound, if he chooses, each member will have, not a part, but all of the "transactions." This would serve to interest in the work those who cannot attend the meetings regularly. It would also be a stimulus to each to do his best work. I earnestly recommend this plan for your consideration, believing that it will be economical and valuable.

If the above plan is adopted, I would suggest the inquiry whether we might not enlarge our Society to include a number of physicians throughout New England, who are interested in Gynecology. They might be able to attend but seldom, yet they might communicate to the Society their best thoughts and report interesting cases. A careful consideration of these matters is all I ask. I would recommend a revision of our list of corresponding members and a systematic effort to get contributions from them.

I take pleasure in announcing that the records and lists of members have been collected and are now in the hands of the Secretary. Our Society begins its third decade in a prosperous condition. May the future be one of increasing prosperity and usefulness. And now thanking you for the generous assistance you have always given me, and the unmerited honor you have conferred upon me, I will close, bespeaking for my successor the same cordial support which you have given me.

The following were elected

OFFICERS FOR THE ENSUING YEAR.

President—W. Symington Brown.

Vice-President—Augustus P. Clarke.

Treasurer—Charles W. Stevens.

Secretary—Samuel N. Nelson.

Committee on Membership—J. F. Frisbie, E. C. Keller, H. O. Marcy.

Pathological Committee—S. N. Nelson, I. W. Starbird, A. L. Norris.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

Treatment of Acute and Subacute Nephritis—The Academy of Medicine.

It is not often that one has the pleasure of listening to such a model of clearness, conciseness and completeness as the paper read by Dr. Francis Delafield at the last meeting of the Academy of Medicine, on *The Treatment of Acute and Subacute Nephritis*. He acknowledged at the outset that he had no new drug to propose or no new plan of treatment to advocate. It was rather his object to determine, if possible, how plans of treatment and drugs already employed were to be intelligently applied in individual cases of the disease; since it was of importance not only that patients should be cured of their disease, but that this cure should be effected as speedily and as completely as possible, or, if the disease was an incurable one, that life and the capacity for labor and for enjoyment should be prolonged to the utmost.

To give an idea of the methods of treatment ordinarily employed, he thought it would be sufficient to quote briefly from a French, a German and an American authority. These were, Labadie-Lagrave, in the *Nouveau Dictionnaire de Médecine et de Chirurgie*, Strümpell's Practice, and Flint's Practice. Most authors, he went on to say after making the quotations, took much the same view of the treatment; that its main object is to make up for the diminished quantity of urine by acting on the skin and intestines, and that the principal danger of an acute nephritis is the accumulation of excrementitious substances in the

blood. Some authors, in addition, believed that they could rest the kidneys while they were inflamed by producing diaphoresis or catharsis, and that such rest would diminish the severity of the nephritis. Some thought that by a sufficiently large injection of fluids the inflammatory products could be worked out of the kidneys; a procedure which seemed to be analogous to the treatment of scouring the blood, as practiced by some eclectics.

Digitalis, while regarded with apprehension by some, was warmly advocated by others as a diuretic, or as a remedy for the febrile movement. Morphine in considerable doses was employed by some for the relief of uræmic attacks; in small doses by others to relieve vomiting and restlessness; while still others deprecated its use under any circumstances. General bloodletting seemed to be restricted by most to the nephritis of pregnancy, and to the very severe forms of the disease attended from the first with high temperature and cerebral symptoms.

The disposition at the present time to direct attention and the treatment to the symptoms of the nephritis, rather than to the nephritis itself; to the dangers of a diminished excretion of urine, rather than to the bad effects of kidneys in a state of acute inflammation, is so general and decided, that he thought it might be wholesome to look at the subject from the opposite point of view, and to direct attention, not to the functions of the kidneys, but to the kidneys themselves. In order to do this it was necessary at once to separate the cases of acute nephritis from those of subacute nephritis; the condition of the patients being altogether different in the two classes.

1. *Acute Nephritis*.—Most of the cases of acute nephritis met with complicate scarlatina, diphtheria or pregnancy. Less frequently the nephritis complicates one of the other infectious diseases or severe inflammations, or it is a primary lesion. In all cases of acute nephritis one morbid change is constant, viz.: congestion and exudation from the blood-vessels. The exudation consists of blood serum, white blood cells and red blood cells, which escape for the most part into the tubes and are mixed with the urine, to a less extent into the stroma of the kidney. The principal part of the exudate is regularly serum, but in some cases the emigration of white blood cells is considerable, and in some cases with a large emigration of white blood cells the exudation of serum is but small.

Having referred to other lesions that may or may not be added to this constant change in the kidneys, he spoke of the symptoms varying according to the severity of the nephritis, and said that, in the very mild cases, the only symptom was a diminution in the quantity of the urine and the presence in it of the exudate from the kidneys—the albumin, casts, and red and white blood cells. In the more severe cases, he continued, the same changes in the urine exist, and there are

added constitutional symptoms, such as fever, prostration, loss of appetite, nausea, vomiting, and anemia. In the still more severe cases there are also headache, delirium, stupor, convulsions, labored heart action, hypertrophy of the left ventricle, a pulse of high tension, and dropsy. In the cases in which the urine is suppressed for a number of days the patients develop alternating stupor and delirium, and pass into the typhoid state. The regular duration of a fairly developed acute nephritis seems to be about four weeks. Its natural termination, whether with or without treatment, is in recovery. But the more severe cases may prove fatal; while the cases in which there is from the first a growth of new connective tissue in the stroma are likely to become chronic.

As to the indications for treatment, in the very mild cases evidently no treatment is necessary, except to keep the patient in bed and on a fluid diet. In the more severe cases it is often proper to interfere in order to secure greater comfort and safety for the patient. The first of the different conditions which may call for treatment is the nephritis itself. It is to be remembered that although the quantity of urine voided is small, its quality is good; for it contains a fair proportion of excrementitious solids to the ounce of fluid; that convulsions and coma belong to the early days of a nephritis with scanty urine, while prolonged anuria is accompanied rather with the typhoid state; that the excretion of urine must naturally relieve the congestion of the kidneys, so that it is better for the kidney to perform its functions than to be at rest; that so long as the congestion of the kidneys persists the quantity of the urine will be diminished; and that a considerable diminution in the quantity of urine continued for one or two weeks is often borne perfectly well. It is not necessary, therefore, to pay attention to the diminished quantity and to try to make the skin or the intestines do the work of the kidneys. It is wiser, by relieving the congestion of these organs, to enable them to do their own work; knowing that the moment they begin to do this their congestion will be still further diminished, and that although the nephritis still continues, the excretion of urine may then be sufficient.

Fortunately, we have at our command means by which the congestion of the kidney can be materially reduced for short periods at all events. These means are: causing the blood to collect at the surface of the body by the application of heat to the entire skin; the use of dry cups, or wet cups, or heat over the lumbar region; the empirical use of calomel or sulphate of magnesia in small doses repeated at short intervals until the bowels begin to move; and the use of such drugs as will diminish the increased arterial tension. While the nephritis is still active, however, it is not to be expected that by the use of any means the urine will be brought up to its full normal

quantity, but only that a sufficient quantity will be passed to ensure the safety of the patient. The febrile movement requires no treatment, while the prostration, loss of appetite, nausea and vomiting call only for rest in bed and a fluid diet. The anemia ought unquestionably to be relieved, but while the nephritis is still active there appears to be no way in which this can be done with certainty. When convalescence is established the anemia readily improves with the ordinary methods of treatment.

The cerebral symptoms are those to which most attention has been directed. There can be no question that they regularly accompany a contraction of the arteries with increased tension and a labored action of the heart. No matter what views one may entertain as to the cause of this change in the circulation, Dr. Delafield believes that treatment is best directed to the arteries themselves, rather than to the uncertain cause of their contraction. There are, fortunately, he said, drugs which act promptly and efficiently for this purpose, and the most suitable of these are aconite, chloral hydrate and opium; and these are preferably to be given in small doses and at regular intervals, so that their use can be continued for some time. It is wise to watch the condition of the heart and arteries and, as soon as the condition of increased arterial tension is developed, not to wait for the manifestation of the cerebral symptoms, but to try and relieve it at once.

The treatment of a case of acute nephritis resolves itself, therefore, into the treatment of the nephritis itself and of the contraction of the arteries which may accompany it. To carry out this treatment he said he could from experience strongly recommend the following routine: The patient is put to bed and restricted to a fluid diet; the entire skin is washed clean every day; for two successive days drachm doses of sulphate of magnesia are given every hour until 1 oz. has been taken, or the bowels begin to move; after this the tincture of aconite is given in doses of 1 minim every hour. Within a few days the albumin in the urine will have diminished, the pulse will be soft, and the dropsy will have disappeared; but the patient will be anæmic. The milk is now gradually replaced by solid food, and iron and oxygen are given.

2. *Subacute Nephritis*.—The distinction between acute, subacute and chronic inflammations, while an arbitrary one, is often of real convenience, and Dr. Delafield regards this as especially true of nephritis. In acute nephritis, as has been seen, he went on to say, the inflammation is an acute and temporary one attended with congestion and exudation. The interference with the function of the kidney is only with the quantity of the urine; the urine that is produced being of good quality. The symptoms are due to the nephritis itself and to the accompanying contraction of the arterial

vessels. In subacute nephritis, on the contrary, the inflammation is subacute and long-continued; there is no congestion; the exudation is of the profuse, almost dropsical, character that we meet with in other subacute inflammations, such as pleurisy with effusion; and there are permanent changes in the stroma and glomeruli of the kidney. The interference with the functions of the kidney is not with the quantity of the urine, for this is often in excess, but with its quality; the proportion of solid matters steadily decreasing as the disease advances. The symptoms are largely due to the effect of the nephritis on the composition of the blood and the nutrition of the body. The anæmia, the dropsy, and the loss of strength are the prominent features of the disease. Contraction of the arteries is absent, or present only at intervals. The cerebral symptoms are chronic rather than acute. It may happen, however, that in the course of a subacute nephritis there will be exacerbations of the inflammation, during which the changes in the kidney and the symptoms are the same as those of an acute nephritis.

Subacute nephritis is especially common as a primary disease and as a sequel of scarlatina and diphtheria. The patients lose strength, they become anæmic, and they suffer from nausea, vomiting and diarrhoea. There may be inflammation of the retina, and the arteries are for the most part relaxed; but may sometimes be contracted. The cerebral symptoms are more frequently chronic than acute, and dropsy is apt to be a marked symptom. The urine may be somewhat diminished, but is often in excess. The specific gravity and quantity of solid matters excreted diminish as the disease progresses, while the quantity of albumin mixed with the urine is considerable.

Some of the patients continue to get worse in every way, and die within one or two years. Some of them exhibit some or all of the symptoms of the disease for weeks or months; then seem to be partly or completely well; then again become ill, and so may go on for many years, sometimes better, sometimes worse. In some of them acute exacerbations of the inflammation may give for a time the symptoms of acute nephritis. A very few seem to recover permanently. The conditions which require treatment in these cases are: 1, the subacute nephritis; 2, the changes in nutrition and the composition of the blood; 3, the dropsy; 4, the condition of the arteries; 5, the cerebral system; 6, the acute exacerbations of the inflammation.

For the nephritis itself the most efficient treatment is the residence of the patient in a suitable climate. The climate should be warm, and the particular locality selected should be one where the patient can lead an out-of-door life. If the patients remain in a cold climate it will be necessary to confine them to the house for much of the time. Except during the exacerbations of the

nephritis, the patients should take as much of solid foods and fats as they can digest. The excessive use of milk and of the mineral waters is to be avoided. It is possible that the use of opium or of the bichloride of mercury may favorably affect the nephritis. The anæmia is a most important symptom. There is a diminution in the quantity of hæmoglobin and in the number of red blood cells. The most efficient treatment for this is the internal use of iron and the inhalation of oxygen, combined with massage and the relief of constipation. With this treatment in many of the patients the improvement is satisfactory, but in some no such improvement takes place. The dropsy may never be more than an inconvenience, or it may constitute the most distressing feature of the case. It is apt to reach its greatest development with low arterial tension and often with a large excretion of urine. In some cases the treatment of the anæmia and the regulation of the diet will answer at the same time for the treatment of the dropsy. In other cases it is necessary to employ different measures.

When a subacute nephritis has lasted for any length of time the quantity of urea excreted falls to 6 or 7 grains, or even less to the ounce. The patient ought, therefore, to pass 70 or more ounces of urine daily. If it is desired to diminish the dropsy by increasing the quantity of urine it is wise not to increase the urine more than will be sufficient to enable the patient to excrete his 500 grains of urea a day. The quantity of fluid which the patient drinks should be regulated, as far as possible, according to the quantity of urine passed; not allowing the former to exceed the latter. In the extreme cases of dropsy we are obliged to purge, to sweat, to puncture the skin, and to tap the serous cavities. But when these measures become necessary it means that the case is an unfavorable one.

The condition of the arteries and of the left ventricle of the heart should be watched throughout the disease. High arterial tension can often be controlled by nitro-glycerine, chloral hydrate, or opium. Low arterial tension can, theoretically, be heightened by digitalis or ergot, but Dr. Delafield has found no advantage in doing this. To avoid the cerebral symptoms it is necessary constantly to watch the excretion of urea and the condition of the arteries. The quantity of urine should be kept large enough to make up for its diminished solid contents, and increased arterial tension should be at once relieved. The acute exacerbations of subacute nephritis are to be managed in the same way as an attack of acute nephritis.

In conclusion, he remarked that, as he had stated at the beginning, he was not able to offer any new plans of treatment. He had simply tried to show that some of the old methods might perhaps be more intelligently applied, and that,

while symptoms had to be treated, this might be done largely with direct reference to the nephritis.

The paper was discussed by Drs. Jacobi, Loomis, Kinnicutt, Roosevelt, Winters, Lawrence Johnson, and others, and Dr. Delafield closed the discussion. In the course of his remarks he said that he had always found one difficulty about the subject in question. Whenever he commenced to talk about acute and subacute nephritis some one was sure to get off on to the discussion of chronic Bright's disease. He thought Dr. Jacobi had made a very good point in calling attention to the comparative frequency of acute and subacute nephritis. It was not by any means almost exclusively confined to scarlatina, as many practitioners seemed to think, but was met with in connection with many of the other acute fevers, and not infrequently as a primary affection also. Many young laborers went about their work while affected with acute or subacute nephritis, not considering themselves sufficiently ill to take to their beds, and thus very serious injury was liable to result.

As regards the matter of arterial tension, he thought it was necessary to draw a sharp line between cases of acute and subacute nephritis. When the affection was acute there could be no question that the quickest way to reduce the tension was by the use of small doses of calomel or sulphate of magnesia frequently repeated. This relief he believed to be due to the effect of the drug on the nephritis itself. Otherwise it was not easy to see how such agents acted, since in order to secure the best results their use should be suspended as soon as a distinct purgative action was produced. In order to relieve the arterial tension the calomel or sulphate of magnesia should be given every hour, just as in peritonitis. This effect having once been obtained, it could be sustained better by aconite in minute doses than by any other agent with which he was acquainted.

The moment that we had to deal with subacute nephritis the conditions were found to be altogether different, and no good results were to be any longer anticipated from the use of the agents mentioned. Here we employed the class of drugs which dilate the vessels, and nitro-glycerine and chloral hydrate were both efficient for this purpose. The use of digitalis did not apply to acute nephritis at all, and in subacute nephritis the indications for its employment had been very clearly pointed out by Dr. Loomis.

(Dr. Loomis had remarked that whenever in subacute nephritis heart trouble was met with we had a right to resort to digitalis or other cardiac tonics; but so long as arterial tension remained such agents would only do harm. If in any case with a tendency to heart failure the digitalis seemed to increase the quantity of urine voided he thought it ought to be employed, and it was perfectly safe to do so as long as this effect was noticed.

If, on the other hand, arterial tension was present, digitalis would always diminish instead of increase the quantity of urine, and consequently it was clearly contraindicated in any such case.)

At the conclusion of Dr. Delafield's remarks the President, Dr. Loomis, announced that the Academy had secured the refusal of three lots for its contemplated new building on 43d street, near 5th avenue, the price of which was \$90,000.

LECTURE.

THE HEATING AND VENTILATION OF THE MANSFIELD SCHOOLS AND CHURCHES.

A Lecture delivered before the Mansfield Lyceum, February 13, 1889.

BY R. HARVEY REED, M.D.,

CITY HEALTH OFFICER, MANSFIELD, OHIO, SECRETARY OHIO
STATE SANITARY ASSOCIATION, ETC.

There are three leading combinations of chemicals that enter essentially into the welfare of the human economy, the absence of either one of which would soon result in death. The adulteration or impurity of either, or a reduction of the normal supply of either one, results in a proportionate injury to the living human organism.

These three combinations are air, water, and food. In previous papers read before this Lyceum and our City Council I have called attention to the importance of a bountiful supply of pure water, and our city authorities have practically demonstrated their appreciation of such a supply by investing the sum of \$190,000 in securing a suitable water supply for our city, which requires an annual outlay of \$5,700 to maintain, saying nothing of the interest on the capital invested in the plant, and yet no one complains, or would ever think of voting to abolish our city water works, which every person concedes to be an absolute necessity.

The importance of a bountiful supply of pure air is second to neither of the other two combinations that must needs be present in order to support human life, and from personal experience and repeated investigations the unwarranted neglect and miserly supply of this, the freest of all of nature's gifts to man, has led me, as your City Health Officer, to inspect the schools and churches of our city, and give you an unvarnished report of their real condition as to heating and ventilation.

In warm countries, where there is little need of protection from the elements, and where open huts serve in place of the "hermetically sealed" houses in our more rigorous Northern climates, there is little need of systems of heating and ventilation, for there the native or his visitor gets a

bountiful supply of God's free pure air night and day, winter and summer, unmolested by the conventionalities of art. Not so in our Northern climates. The open hut is replaced by the device of the city architect, who at once commences to rob our people of their pure air, and study how they can build all sorts of fancy structures of the latest and most approved style, in which they can "hermetically seal" their inmates from the oceans of pure air that surround this "human can they call a house," and thus not only starve them of oxygen, but poison them in their own excrement—the carbonic acid gas they exhale from their stunted lungs at every breath. Could the dead that lie in yonder grave-yard, who have fallen victims to illy planned and improperly heated and ventilated dwellings, lift their voices in one accord against the architects who by their mistakes have forced them to a premature grave, nothing but an Ashland County jury would save them from conviction of murder in the second degree.

In making these inspections I have endeavored to "hew to the line, let the chips fall where they may." I have inspected all the churches, and each room in every school-house in the city, in person, and noted the exact plan by which it is heated and supplied with pure air, or air of any kind, and have tried to briefly point out their faults and also note their good qualities, and will close the paper by giving you a simple, yet scientific method, illustrated by charts and practically demonstrated by a model, whereby you can heat your buildings thoroughly, and at the same time flood them with abundance of pure air.

Before giving the details of these inspections, it is only just that I should say that in the main the people are not to blame for the almost universal defects found in the heating and ventilation of their schools and churches. They are not expected to know, nor to study up those problems, and most naturally depend on the architects for all the plans and specifications regarding their buildings, and hence they are just the persons the sanitarians are looking for, and to whom and of whom they have a word to say. The architect comes to you with a beautiful perspective, every inch of which is elaborately detailed down to the tacks and paint. So much must be stoned from

Cleveland, Cincinnati, or New Hampshire; so much must be brick of the latest pattern, burned with *hickory wood*: this particular part of the edifice must be finished with boards cut from the cedars of Lebanon, that part must be furnished with choice butternut from the valleys of the Mohican, the windows must be dappled with glass of many colors, the walls ceiled in with the best of plaster, and furnished with a specially hard finish; the floors must be of the finest oak, inlaid with hard woods of many kinds and colors; and finally this great and costly mansion is to be heated according to the latest and most approved methods.

That is usually all that is said and about all that is done in regard to supplying you and your family with the real necessity of life—the most important part of the whole edifice. I mean to say that the average architect pays little or no attention to the heating and ventilation of your building. He can tell you all about the ornaments and fancy fixings on the cupolas and cornices of your house, and will insist that they be mathematically correct, yet the heating and ventilation, on which depend your life and health, he leaves to some furnace peddler to complete “in the latest and most approved manner.”

Go with me now, if you please, for a few moments, while I take you from church to church, and school-house to school-house of our prosperous city, and examine into and study from a practical and scientific standpoint the legacy the architects have left this city in the way of heating and ventilation in a class of buildings that should be the pride of every city and above all other public buildings the very type of perfection.

On December 18, 1888, I visited and examined the St. Luke's Lutheran church, which is not yet completed, and which was planned by an eminent architect, Mr. Wm. Gibbon Presto, of Boston, Mass. I found the church was heated by two *Ætna* soft-coal furnaces, made at Springfield, O., which are supplied with cold air from two windows leading into the coal rooms in the basement, over which the air must pass before entering the heater. The lecture-room of the church is heated from these furnaces by hot air, which is conveyed in conduits coming in from 4 to 7 feet from the floor. At the rear end of the lecture room is a fire-place, and just beside it a foul-air register near the floor and opening into the furnace at that end of the church. At the front, or pulpit end of the lecture-room are foul-air ventilators located about 3 feet from the floor and opening into conduits that pass through pillars near the pulpit in the auditorium and open into the garret, which connects with the open tower. The one of these passes a part of the distance near the furnace, which aids some in warming its contents of foul air, and thus assists in its upward movement, while the other is not provided with any means of heating whatever. In the auditorium the

warm air comes in at the floor, while the foul air is allowed to escape by means of registers placed about 3 feet above the floor and opening into the attic, with no provisions for heating the column of cold air and thus favoring the exhaustion of the foul air from the main room.

REMARKS.—With no provisions for protecting the pure air from the dust of the coal and the ashes of the furnace it begins to get fouled before it enters even the hot-air chamber of the heater, and is an excellent method to carry quantities of dust into the rooms to be heated and ventilated. Whilst the lecture-room receives a pressure of warm air from the furnace the fire-place in the rear end of the church furnishes a most excellent method for the escape of the stratum of cold foul air that always finds a place at the floor, and it should always be kept burning when the room is being occupied. The foul-air ventilator that opens into the furnace should never be left open after the room is once heated, and under no circumstances when occupied by an audience, as that only serves to convey the *cold foul* air back to the furnace to be reheated and returned in all its impurity to be breathed over again by the audience. The other foul-air registers should have been placed at the floor, instead of 3 feet above the floor, and supplied with means for heating the column of cold air contained in them. As it is, they leave a three-foot stratum of cold foul air in the rooms they are intended to ventilate, even when the ventilators work. But you must remember they will not work until there is a sufficient pressure of air from within to lift the cold column of air they contain, and if that is at any time greater than the pressure within, they will allow their contents to descend into the room to the discomfort of the audience.

In the lecture-room, however, the fire-place when in use serves this purpose as far as it goes, and not unfrequently creates such a draft as to cause the cold air to descend in the foul-air ventilators to supply and equalize the vacuum thus induced, especially when the supply from the furnace does not equal the amount of air exhausted by the fire-place. It must be remembered that a grate with a fire in it, and foul-air flues without fire, will not work harmoniously in the same room at the same time; hence one or the other, as a rule, should be closed.

On December 26, 1888, I examined the Baptist church, which was built in 1864, but by whom it was planned I was unable to learn at this time. I found it was heated by a Ruby soft-coal furnace, which was supplied by fresh air from the outside by two 8x8 inch cold-air conduits, whilst the warm air was admitted into the auditorium by five registers placed in the floor near the rear end of the room, to which the warm air was conveyed by five 10 inch hot-air conduits. Two foul-air registers were placed in the floor near the front

end of the auditorium, one on either side, and connected with a conduit that returned the cold foul air to the furnace to be reheated and returned to the room again. These, however, had been abandoned some time since and closed up. Two 14x16 inch registers were placed in the ceiling, which allows all the warm pure air to escape into the garret, while the cold foul air is allowed to remain in the lower portion of the room. The janitor, however, has discovered that in order to heat and keep the auditorium warm he must close these registers, which serve him well when the room gets too warm and he desires to cool it off rapidly.

REMARKS.—By enlarging the cold-air inlet of the furnace, and opening the foul-air ventilators at the floor into the two chimneys at the front end of the church, which are always kept warm by stoves, a very great improvement could be had at a minimum amount of expense in the way of heating and ventilating the auditorium. The lecture-room is heated by stoves, with no provision for either the ingress of pure air or egress of foul air, except by the windows, which needs no comment at this day and age, as a means of ventilation, as they are always an objectionable means of obtaining fresh air, except in very warm weather.

On January 10th and 11th, 1889, I inspected the Congregational church, which was built during 1871-3, at a cost of nearly \$125,000, under the direction of architect G. P. Randall, of Chicago, Ill. The auditorium is heated by steam from coils of pipe running under each seat, which furnish ample means for the desired amount of heat. The original plan provided for seven large ventilators placed in the comb of the roof and leading down into the top of the auditorium, and so arranged by valves as to be opened or closed at will, whilst the foul air was expected to beat a hasty retreat through two small registers, 12x12 inches, placed in the base-board of the auditorium and opening into the cellar.

By this theoretical plan it was intended to let the fresh air in at the comb, which being cold and consequently heavier, would descend into the auditorium, driving the foul air out at the floor into the cellar. But, like the old spook story of our childhood, when a certain boy undertook to scare another lad while he was passing through a certain piece of timber land, it was a failure. Having secured a sheet he placed it over his head and lay in wait for his victim. But a pet monkey decided to imitate the performance, and, unseen, followed his master to his hiding place, with a pillow-case over *his* head. Just as the victim approached, the trickster chanced to spy spook No. 2, and instead of scaring his victim, became frightened himself, and started to run with all his might, followed by the monkey, while the victim enjoyed the fun and egged on the race by shout-

ing, "Run, big spook, or little spook will catch you."

So in this method of ventilation, instead of the fresh air coming in at the comb and supplying the auditorium, the warm air rushed out, and instead of the foul air passing out through the little registers at the base-board, the cellar air rushed in, and we had a reverse order of affairs throughout, as in the old spook story. These are only the result of natural laws, however. The warm air being lighter rises and escapes through the comb ventilators, there being no provision made by the architect for a supply of fresh air a vacuum is the result, and the equilibrium is established by the cold air rushing in from the cellar through the foul-air registers, as well as through the doors and windows. The janitor, however, found it impossible to heat this room with the comb ventilators open, and in order to accomplish his duties satisfactorily, closed them and supplied the auditorium with fresh air by means of doors and windows.

The lecture-room of this same church is heated by stoves, and has no supply of fresh air, except through the doors and windows, whilst the warm air is allowed to escape, as usual, at ventilators placed near the ceiling, and the foul cold air is allowed to remain at the floor for the benefit and edification of the audience.

REMARKS.—It is no doubt plain to every one here to-night that the heating and ventilation of this church is a practical failure. It is true you heat the church, and, as managed by the janitor, you get some fresh air from promiscuous sources, and allow a part of the foul air to escape, none of which can be credited to the original plan, which in and of itself cannot be recommended as a desirable method of heating and ventilating.

On January 15th, 1889, the First Presbyterian church was inspected; it was built in 1858, but by whom I am unable to inform you. This church is heated by two Montrose hard-coal furnaces, which are supplied with a small quantity of fresh air from the outside, but the mechanism of the furnace is such that the air is frequently contaminated with gas and dust, and always so overheated as to make it very disagreeable to inhale. The provisions for ventilating the auditorium are a few small ventilators, placed near the ceiling, which permit a quantity of the warm air to escape and leaves the carbonic acid near the floor to soothe the innocent audience to sleep while they may be trying to listen to the most interesting sermon. Hence the objectionable method of window ventilation must be resorted to as the less of two evils, to relieve the so-called "closeness of the air" and stupor of the audience from the poisonous effects of large quantities of carbon dioxide. The lecture-room is heated by direct radiation from the same heaters, and has no system of ventilation, except the windows and doors.

REMARKS.—In this case it is plain that the church is improperly heated and is devoid of anything like adequate ventilation, whilst large quantities of coal are wasted annually in trying to make the church approximately comfortable.

The St. John's German Evangelical church was visited and inspected January 18, 1888. This edifice was built in 1870, and is heated by a Barnes' soft-coal heater, No. 64, which secures its supply of air from the Sunday-school room, which it heats by radiation, and this air, after being vitiated by the Sunday-school scholars, is heated and conveyed to the auditorium in a second-hand condition for the congregation to use during the sermon. No provisions are made for ventilation except by windows in either the auditorium or Sunday-school room.

On the same date I visited the St. Peter's Catholic church, a handsome edifice, built in 1870; this is heated by stoves, and has no provisions for ventilation except the doors and windows.

REMARKS.—The congregation is a large one, and the architectural finish of the interior of the church is very costly as well as attractive, but the supply of pure air for the hundreds who congregate there from day to day has been wholly left out of consideration except by the faulty method of window ventilation.

On the 21st of January, 1889, I visited the Episcopalian church, which was built in 1847, and has had some repairs since that time. It is heated by one Crystal furnace, manufactured at Troy, N. Y., and one Sayer furnace, made at Montrose, Pa. The former takes its cold air from the cellar, which is in quite a dilapidated condition, and is in turn supplied by a hole in the wall on the west side of the church. The Sayer furnace is supplied with cold *foul* air from the rear of the auditorium, whilst the pure air from outside is carefully avoided, except so much as may steal into the foul air register from the outside door of the church. There are no other provisions for ventilation except the doors and windows. The Sunday-school room, built two or three years ago, is heated by stoves, and ventilated by the door and window system.

REMARKS.—In the one furnace the impurities of an old and musty cellar are conveyed with the air to the furnace, heated, and forwarded to the auditorium, while the other furnace is employed to reheat the foul cold air of the church and return it to the unsuspecting audience to be breathed over and over again during each service.

The same day I inspected the United Presbyterian church, which was built in 1885, and planned by Richard Vaux, of New York City.

It is a handsome, well-arranged edifice, heated by two hard-coal "Richmond Triumph" furnaces, Nos. 30 and 27, built at Norwich, Conn. More care than usual has been observed with these furnaces, to exclude all the pure outside air possi-

ble, and instead the one is supplied with cold foul air exclusively, taken from the auditorium, reheated, and returned to the audience, while the other is supplied with air from the hall leading off the main hall to the lecture and Sunday-school rooms. Owing to the necessity of having the front door open as the people come and go, a small supply of outside air finds its way to this furnace at the opening and closing of each service.

REMARKS.—By means of openings in the ceiling and the opening of windows at the top, they are enabled to retain a large quantity of the cold foul air near the floor, and allow a great and unnecessary waste of the warm pure air through these openings. If the church authorities would close all the top openings of their rooms, keep them closed except when they desire to cool their church, supply the furnaces with fresh pure air from the outside, empty their foul cold-air into the ventilating flue instead of heating and returning it to be breathed over again, they would find a reduction in their coal bills, and a large decrease in the drowsiness of their congregation when confined for any length of time in the auditorium.

On January 21, 1889, I examined into the heating and ventilation of the Methodist Episcopal church, which was built by Mr. Hershisser, of this city, about 1868. It is heated by two hard-coal furnaces. One is a No. 5 Sayer furnace, built at Montrose, Pa., and the other is without name, so far as I could see, but is much like the Sayer heater. The former is placed in the library, and when the library window is open, it is supplied with fresh air from the exterior of the building; but when the window is closed, it is without a fresh-air supply, and must draw its air from the library and lecture room with which to supply the auditorium. The other furnace is supplied with fresh air by a conduit about a foot square, which receives its supply from the outside by means of a window. There is no provision whatever for the escape of foul air from the auditorium except through the doors and windows. Two small registers have been placed at either side of the auditorium on about a level with the tops of the windows, which allow quite a quantity of the *warm pure-air* to escape, and thus aid in cooling the room and wasting the fuel. The lecture room must depend entirely on door and window ventilation for the purification of the air.

REMARKS.—By changing the registers and placing them at the floor, making them several times larger, and supplying both furnaces all the time with fresh air from the outside of the church, the auditorium could be very greatly improved with regard to its heating and ventilation.

The Christian church was examined on January 22, 1889. The erection of this church dates back to a period before the civil war; the exact date I was unable to obtain. It is heated by a

Sayer furnace No. 5, supplied from the floor of the auditorium with *cold foul-air*, which is allowed to escape through a register in the floor at the west side of the church; this connects with a cold air conduit coming from the exterior of the edifice to the furnace. No other provisions have been made for the escape of the foul cold-air except the doors and windows.

REMARKS.—In this church we have a mixing of "good and evil," as it were. So far as supplying the furnace with air from the outside is concerned it is good, but when it comes to contaminating the same with vitiated air from the auditorium, it is evil. The vitiated air should be conveyed to a ventilating flue and allowed to escape.

On January 22, 1889, I visited the Evangelical Lutheran church, which has been recently repaired. This structure is heated by two "John Grossius" soft-coal heaters, made in Cincinnati. The Sunday-school room is heated by radiation, and ventilated by doors and windows only. The auditorium is heated by fresh warm air, which enters the room by means of registers in the floor. There is no provision for the escape of foul air except by the doors and windows. An opening in the garret is in the interest of the coal dealers, as it necessitates the use of more coal to heat the church, owing to the great loss of warm air, whilst the corresponding increase of carbonic acid keeps up a slow process of poisoning the audience.

On the same day I visited the English Lutheran church, which is an old-style edifice, built in 1856, and soon to be replaced with a new one.

This building is heated with a Sunbeam Challenge furnace, from New York. The furnace is placed in the lecture room, which is heated by radiation, and ventilated by doors and windows, while the auditorium is supplied with foul air taken from the lecture room, and heated and sent upstairs. There is no provision for the escape of the foul air except through the windows and doors of the auditorium, which is supplied with a sort of a safety-valve attachment in the way of a trap door in the ceiling, which is very convenient to waste the surplus heat of the room when the pressure gets too high.

On January 22, 1889, I visited the church of the Believers in Christ, which was planned by the pastor, Rev. Sorg, and built in 1887. This plain but neat little edifice is heated by a Montrose furnace and supplied with fresh air from the exterior of the building by means of a 15-inch vitrified pipe conduit. The foul air is removed from the lecture and Sunday-school rooms and auditorium by means of four foul-air registers placed at the floor and opening into the ventilating shafts. The auditorium is also supplied with four additional registers, placed near the ceiling, which are only used to cool the church when it gets overheated.

REMARKS.—I cannot pass this building with-

out congratulating this congregation on the advancement they have attained over all the other churches in the city, with perhaps one exception, in regard to the heating and ventilation of their building.

On January 24, 1889, I examined the Associate Presbyterian church, which is a very small edifice, built in 1888; it is heated by stoves, and ventilated by doors and windows. Four 12×12 inch registers have been placed in the walls near the ceiling, and are only mentioned to be condemned, except for cooling off the church when it is overheated.

On the same day I inspected the Reform Presbyterian church, which was planned by a Mr. Rumbaugh, then of this city, and built in 1885. This church is heated by Goff & Co.'s hard coal, hot-air, blast furnace, which takes the fresh air from outside the church, heats it, and delivers it to the auditorium at the floor near the rear of the room, while the foul cold-air is taken from the front and lowest part of the room, and exhausted by means of a foul-air shaft, which is heated by a small stove used in one of the side rooms of the church. In the foul air conduit is an arrangement by which the cold air can be turned into the fresh-air conduit leading to the furnace. This is used only while heating the church, when it is cut off from the furnace and again opened into the foul-air shaft, which is or should be kept open during the presence of an audience in the auditorium. The Sunday-school and lecture room is heated by a Grossius heater, manufactured in Cincinnati, and is supplied with fresh air from the exterior. Unfortunately, however, there was no provision in this room for the escape of the foul air, except by the doors and windows.

REMARKS.—With the exception of the Sunday-school room, the system for heating and ventilation used in this church is the best in the city, whilst the Sunday-school room could easily be remedied by placing a foul-air register in the ventilating shaft of the chimney.

It will be observed that, with two exceptions, there is not a church in our city that is provided with adequate means for the prompt removal of the carbon dioxide, the deadly poison that is exhaled with every breath. When we remember that it requires at least 1,500 cubic feet of pure air every hour to supply one human being, and when we know that the average movement of air through a conduit of 1 square foot capacity under ordinary circumstances, in mild weather, is about 150 feet a minute, and again take into consideration the miserly holes that are required to do this duty in supplying the majority of our churches, we are not surprised that people get sleepy when they attend church. It would be just as reasonable for each congregation to elect a committee annually, whose duty should be to give each mem-

ber a dose of morphine every time they enter the church, in order to stupefy them during the sermon, as to allow the ventilation of their churches to remain as they are, and poison their members with a drug that is even more dangerous than any of the modern narcotics, to say nothing of the disgusting and filthy custom of breathing and rebreathing the foul exhalations of their neighbors.

I have no doubt this lecture has already reached proportions that may weary some of you at least, but the importance of the subject is such as justifies me in trespassing still further on your patience, and hence I have left the most important part of our topic for the last.

When we remember that the youth of our city spend the best part of their days (from 7 years to 21 years) in our school-houses, and that among them is your daughter or my son, whose life and health depend on the perfection of their sanitary conditions and surroundings, it is sufficient excuse for our dwelling longer on this subject, and examining into their real condition and merits from a strictly sanitary standpoint. I shall try, however, to group them, and thus save time and space.

The first two school-houses examined were the Marion Avenue and John's Addition (new building). Both of these buildings have just recently been constructed, and were planned and built by Mr. F. D. Webber, of this city. As they are practically heated and ventilated on the same plan, I will consider them together in order to save time.

Each room is heated by a Grossius soft-coal heater, placed in the room to be heated, and supplied with cold fresh-air from the exterior of the building, conveyed to the heater by a tin conduit some 8 or 10 inches in diameter, with a perforated diaphragm placed near the exterior opening to lessen the amount of air admitted. This air passes through the hot-air chamber, and out at the top of the stove into the room. A number of foul-air ventilators are placed in the base-board at the floor, which the contractor informed me opened into the space beneath the floor, and from there into the foul-air shaft. These registers at the floor are 15×5 inches with one exception, which was 12×10 inches, and placed in the baseboard near the floor, and opened directly into the ventilating flue, which was warmed by the chimney.

REMARKS.—In the first place, the fresh-air supply was entirely too small for the number of pupils contained in each room, to give them the required amount of air, and the result was I found the teachers were in the habit of raising the windows to admit fresh air, at the expense of some unfortunate child taking cold from a draft, or being uncomfortable to say the least.

In the second place, I found that almost invariably the cold air was coming *in* at these foul air registers, placed around the room at the floor, instead of going *out*, except the ones opening into

the ventilating flue direct, in which there was a strong outward draft. This fact necessitated the keeping of these closed, as they made the room very uncomfortable when left open. I think we can attribute the failure of these ventilators to work as designed to three possible causes:

First, that their size is too small, and the space between the floor and the ceiling is not sufficient to favor an outward draft.

Second, that the ventilating flue into which they emptied was too small, or not sufficiently heated to establish a draft under the circumstances, and

Third, that the supply of fresh air was not sufficient to supply the exhaust through the direct ventilator and the open transoms above the doors, and at the same time produce a draft through under the floor.

Whilst these two buildings are the best ventilated school-buildings in the city, yet I would recommend more fresh air, which should not be heated so hot while passing through the hot air chamber as it now is, and either no ventilators opening into the space beneath the floor, or if there are, to have them larger, with more space beneath the floor, with a well heated foul air shaft in order to secure a constant and perfect exhaustion of the cold foul air. As the buildings now exist, I would close all these floor ventilators except the one opening into the ventilating shaft direct, and make that one opening into the foul air flue at least two or three times larger. Whilst this would not secure perfection in heating and ventilation, it would be a vast improvement on the present, and avoid the dangerous and unsanitary habit of opening the doors and windows to obtain fresh air.

On the same date (January 22, 1889) I visited and examined the High School building, and on the 23d the Fourth Ward building, which we will consider together, as they are both heated and ventilated on the same plan. These buildings were erected some fifteen years ago by Mr. Hershiser, of this city, who put in a Boston system of ventilation. The rooms were all heated by a Grossius heater, supplied with fresh air from the exterior, while the foul air was *intended* to be removed by small registers, 18×4 inches, placed in the baseboard at the floor, and opened into a 3-inch or 4-inch tin conduit that descended into a 6-inch tin conduit placed beneath the floor, and which finally opened into the ventilating shaft.

REMARKS.—The same remarks hold good in regard to these buildings as to the former as regards their fresh-air supply, and the system of getting rid of the foul air is a total failure. Excepting the little ventilators that open directly into the ventilating shafts that were warmed by the chimney, there was no outward draft whatever, whilst in many of them that opened into a cold ventilating shaft there was a strong current of cold air coming in, which kept the floor cold

and uncomfortable. The same recommendations would apply to these buildings as to the former ones, which we are certain could still be improved by having furnaces placed in the cellar to supply the necessary amount of fresh air properly warmed, and thus avoid the necessity of carrying the coal up stairs and delivering it all over those large buildings as is now the case, saying nothing of the increased danger of fire by so many stoves.

On January 22, 1889, I examined the old school building in John's Addition, and on the 23d the old Normal School building, which we speak of only to condemn. They are both heated by stoves, with no provisions for fresh air, or the escape of the foul air, except at the doors and windows. In these buildings the air was almost intolerable, and the sooner they are condemned for school purposes the better it will be for the rising generation that must now be incarcerated in them from day to day.

The Second and Third Ward buildings were examined on January 23, 1889. Both were heated by the Grossius heater, which was supplied with fresh air from the exterior the same as the other buildings already described. In the old part of the Third Ward building the foul-air ventilators were placed at the floor as in the former buildings, but opened into the hollow wall, instead of a ventilating flue, which connected them with the garret. Some of these ventilators were working all right, but the majority were admitting cold air, instead of exhausting the foul air. In this building there were no ventilators opening directly into foul air shafts. In the new part of this building there were no foul-air ventilators at the floor, but a retrograde metamorphosis had apparently been established by placing three ventilators in the wall near the top of the room, whereby the foul air was left in the room, and a large portion of the warm pure air wasted.

In the Second Ward school building the new part has a foul-air register up stairs, 18 x 12 inches, opening into the hollow wall near the chimney, whilst the old part has no foul-air ventilators at all, and no registers, except some in the top of the room which, as usual, waste fuel by cooling the room and leaving the foul air in it. I found one 8 x 10 inch ventilator opening into the smoke flue at the floor up stairs in one of the rooms, while some of them were not provided with any kind of ventilation except the already so frequently condemned door-and-window ventilation.

On the same date we examined the last one of the city school buildings, located in Newman's Addition, which was built some ten years ago, and was heated by a Grossius heater, and supplied with fresh air from the exterior as usual. In this building there was an opening in the ventilator in the cellar, which very much interferes with its duties in the school-rooms, where it was most needed. In the lower room a foul-air register

opened into the ventilating flue at the floor, but was so filled with dirt as to completely stop all exit of air through it. In the same room were a few small registers placed back of the teacher's stand, and located about halfway between the floor and ceiling, thus allowing the warm air of their room, with as much of the foul air as chanced to rise that high in the room, to escape, whilst from these to the floor was a 5 or 6 foot stratum of foul air which had no means of escape, and which was additionally cooled by reverse drafts of cold air which invaded the room very frequently through these upper ventilators. The up-stairs department was heated and ventilated on practically the same plan, which resulted in the teachers having to depend on window-and-door ventilation for their pupils.

In all these inspections, in which I was assisted by our worthy Superintendent of Instruction, Prof. Simpson, while examining the school buildings, you will observe I have examined fifteen churches and nine school-houses, every one of which I visited in person, from the cellar to the garret, and examined carefully their systems of heating and ventilation, and when necessary actually tested the drafts and currents of air by proper methods, to satisfy myself of their exact course; and whilst a few of them are fair, I have failed to find a single one complete, and the majority of them are simply horrible!

The question now most naturally arises after all these examinations, How shall we completely heat and ventilate our public buildings? In answer to this question, I will say there are three prime factors that must be duly considered. They are:

1. Uniform heating throughout each room.
2. Abundance of pure air for every person.
3. Prompt removal of foul air from each room.

Then, after having secured these, there are four other factors that must not be neglected. They are:

1. Safety.
2. Economy.
3. Durability.
4. Simplicity.

Having taken it for granted that we have secured *all* these, we will now proceed to answer the question of "How shall we completely heat and ventilate our public buildings?"

By a series of colored charts, and after having shown you the faults of your public buildings, I will continue to illustrate the complete plan, which involves the correct scientific principle of heating and ventilation, by the aid of these charts. Having done that, I will endeavor to confirm my statements by a practical demonstration of both the true and false principles of heating and ventilation by a model house. Before we take up the charts, permit me to say that in a properly heated room there should not exist in

any part of the same room a difference of over 5° to 10° , including the ceiling and the floor.

Provisions should be made to admit at least 1,500 cubic feet of air every hour for each occupant of a given room, which can easily be calculated when we know that on an ordinary calm day about 150 feet of air passes through a conduit one foot square in a minute, or in other words, 9,000 cubic feet, or just enough for six persons for a single hour. In addition to supplying the pure warm air to a room, there should be ample means for the prompt removal of all the foul cold-air, and under no consideration should the carbonic acid be allowed to exceed (and continue at that point) 10 parts in 10,000 of air, and much better if it is prevented from exceeding 5 parts in 10,000, especially in our school rooms. But the real facts are that it is seldom kept so low as 10, and often reaches 20 parts, and even more, to 10,000 parts of air.

If you will turn your attention to these charts, which have been carefully prepared from practical results of a long series of chemical and thermometrical investigations, and show the average relative purity of the air, as well as the temperature of the same, under the various systems of heating and ventilation they represent, you will, perhaps, more fully understand what I desire to make plain to every one here to-night.

In chart No. 1, you will readily recognize a familiar every day picture of the mother at her ironing, with a red-hot stove near by, and a window near the stove, let down from the top, through which is escaping a volume of hot air at the upper part of the opening, while a stratum of cold air is pouring in at the lower part of the opening to supply the vacuum produced by the escape of the former. From the lowered window of the leeward side of the room is a constant volume of cold air rapidly descending to the floor, and at the same time keeping that side of the entire room cold by forcing the warm air to the opposite side of the room. The mother's face is flushed with the heat from the stove and the exercise of the ironing, for which reason she has just opened the window to get a breath of fresh air, as she terms it. While the upper portion of her body is too warm, her feet are cold, and at the same time her little child is crying with the cold as it tries to play on the floor around her feet; and yet that mother goes to bed with a cough, and her child suffers with catarrhal trouble, and she "can't for the life of her see how it comes."

Only last Saturday I was visiting a child with congestion of the lungs, and lying in a cradle near the floor. I remarked that the room was not warm enough for it, when they promptly pointed me to the thermometer that was hanging about six feet from the floor and registered 72° Fah. I laid the same instrument on the floor be-

side the cradle for ten minutes, and showed then it registered 56° , or a difference of only 16° , and yet they were surprised that their child had been taken sick, for they were sure it had never been out of the house or exposed in any way to the cold.

Chart No. 2, represents the good old-fashioned grate "of ye olden times," when a man never lacked for exercise while trying to keep warm by it, for just as fast as he got one foot warm by crossing his legs and holding his foot up to the fire, his other foot would get cold, and he would have to change off and warm that, and at the same time while his face was flushed with the heat, the cold chills were playing up and down his back until he must turn that to the fire, when the other side would get cold; and thus he must ever turn like the spit before the fire to keep warm. You will readily see by this chart that it divides the room into two triangles; as the rays of heat travel in direct lines and the heated air rises, the natural consequences are that the side of the room next to the grate is warm from the level of the fire to the ceiling, while the opposite side is cold almost from the ceiling to the floor. You will see that each one of these form the perpendicular of a triangle; while we have a cold floor on the one hand, and a warm ceiling on the other, forming the bases, and a direct line from the fire to the opposite upper corner of the room forms the hypothenuse that divides, as it were, the cold foul-air of one-half of the room from the warm air of the other. It is no longer a question that the fire-place alone is a very defective method of trying to heat and ventilate a room.

We will now pass on to chart No. 3, which represents an attempt at heating a room without stove or grate. In this case the architect has decided to heat the room with warm air admitted at the floor in the centre of the room, and in full accord with the old theory that the foul air *rises*, he has decided to permit that to escape at the top of the room, just as I have found to be the case in several of our school rooms and churches in this city. Indeed, I am sure you would be surprised to find how many intelligent people, even at this day, will appear to be thunder-struck when you tell them the warm pure air is at the top of the room, and the foul cold air at the bottom of the same. Only a few days ago I met a gentlemen who still contended that such was the case, and insisted on not being reconciled to believe anything else. I asked him if he had ever made or saw made any chemical analysis of the air of various rooms? He said, "No." I then asked him how he knew that he was correct? He replied, "Why, because the physiology says so." That is the secret of the whole business. Some person said so, and hence, it must be so, whether it is so or not, and the general result is that no person takes the pains to investigate the

facts and correct the popular mistake, and consequently custom has to some people made a law.

You will see by this chart that like the smoke from the fire in the Indian's tent, the heat arises to the top of the room and out of the first opening it finds, and if the exit is equal to the inlet, the remainder of the room continues cold, and the foul air it contains remains unmolested. In trying to overcome this the architect has decided to change the plan of ingress of the warm air to the opposite lower side of the room from the place of exit at the ceiling, with a view of making the warm air travel a greater distance through the room, but the improvement, as you will see by chart No. 4, is so slight, and the results so unsatisfactory, that he must seek some other method in order to accomplish his ends, and warm the room and remove the foul air.

In chart No. 5, you will observe he has, in part, accomplished this by lowering the place of exit, and just in proportion as that is lowered, the portion of the room above is heated and ventilated, while that portion below is imperfectly heated and contains a stratum of foul air. You will remember I called attention to this fact in my report of the condition of the St. Luke's church, of this city, which has its foul-air registers placed some three feet from the floor, and in consequence will leave an equivalent stratum of foul air in the room. You might just as well set a barrel on end and try to empty it by boring a hole, say a foot from the bottom. Of course, the water would all run out to a level with the bottom of the hole, which would leave a foot of water remaining in the barrel. The same is just as true of cold foul-air in a room.

In chart No. 6 the sanitary engineer has solved the problem and placed the inlet and outlet of the air both at the floor. The warm pure air is taken in at the floor and the foul air is removed at the floor at the opposite side of the room, and the consequence is that the entire room is heated and ventilated evenly throughout. That this method of heating and ventilating a room is a success is beyond question, and if there is a single person in this audience here to-night who questions its practicability, all I will ask him to do is to come to my house and I will show him the whole system at work in my own house, where it has proved successful beyond a question, and, besides, has very greatly diminished my coal bills, over the old plan of top-ventilation, which preceded it in the same house, besides supplying each inmate with over 1,500 cubic feet of warm pure air every hour, and removing the foul air to a standard not exceeding 4 or 5 parts in 10,000 at any time, day or night. Perfect as this plan is, it has still been improved upon, not in the way of ventilation, but in the economy of fuel and the comfort of the floors, by running the cold foul air through registers placed just beneath the windows and opening into

the space beneath the floors, and from there into the foul-air ventilator, which warms and dries the floors, and thus is a saving on the fuel by causing this partially warmed air to pass through under the floor before it escapes up the ventilating shaft.

This ingenious and economical method of heating and ventilating was suggested and put into practice by that veteran sanitary engineer, of Toledo, Ohio, Mr. Isaac D. Smead, who has done more to develop and perfect the true scientific principles of heating and ventilating buildings than any one man on this side of the Atlantic Ocean, if not in the world.

As the old saying is, "Seeing is believing," hence before closing this lecture I will show you, by the aid of this model house, beyond a question that the principles I have endeavored to impress upon you are correct and based on scientific facts. You will observe that this is nothing but a tin box, made air tight, in the shape of a house, with a glass front in it. Here at this end is an opening at the floor to admit fresh air. At the opposite end is an opening at the floor leading into a chimney or ventilating flue, just as a fire-place or grate would. At the top of the room are six openings to represent windows. Now I will take this small wax candle, and from an opening in the floor I will place it in the lower part of the room near the floor and close the opening. I will now close all the windows and just leave the opening at the floor for pure air and the other opening at the floor for the escape or foul air, open, and you will observe the candle burns brilliantly and uninterruptedly, or until it is consumed.

I will now close the exit for foul air at the *floor* and open all the six windows at the *top*, and you will find that the candle will burn for a while, but the carbonic acid (which is formed by the burning candle in the same manner as it is by a breathing person) being heavier cannot rise against gravity and escape at the windows, and hence settles down at the floor, and just as soon as it fills the room to the height of the blaze in the candle, the light begins to turn blue, flickers, and finally dies from carbonic acid poisoning.

Again, if I close the opening for the admission of pure air at the floor, and also the opening for the exit of foul air at the floor, and open the six windows, all at the top of the room, the candle goes out much sooner than in the previous experiment; for in this experiment the supply of fresh air is diminished as well as the escape of the carbonic acid prohibited, and here you see the folly and unscientific principle of opening the windows at the top to ventilate a room.

Now, if I close the windows at the top, and also the opening for the foul air at the floor, and only open the ventilator for the admission of pure air, the candle is again extinguished by the foul air which accumulates on the floor of the room,

as there is no circulation of air in this case, and the poisonous gas cannot escape. Or, if I reverse this experiment, close the opening for the admission of pure air, and open the foul-air ventilator at the floor, the candle again dies from carbon dioxide, which for want of circulation cannot escape, and the result is fatal to the candle.

It seems to me that these experiments which have been strengthened time and again by chemical analysis, are sufficient to demonstrate to any unbiased mind the fallacy of so-called top ventilation, as compared with floor ventilation. I am sure if the principles here demonstrated by this simple model were put into practice in our city schools and churches there would be fewer of our school children coming home in the evening with headache and general languor, and fewer drowsy persons in our churches during divine service than we see now, which can usually be attributed to defective ventilation and the result of a slow process of poisoning from carbonic acid, saying nothing of its effects on weak lungs and its general depression on the whole economy. For let us remember before we close, what we said at the beginning of this lecture—that pure air is one of the three essential compounds for the support of human life.

Mansfield, Ohio, Feb. 11, 1889.

THE ETIOLOGY OF DIPHTHERIA.

Read before the Section for Clinical Medicine, Pathology, and Hygiene of the Suffolk District Medical Society, Feb. 13, 1889.

BY SAMUEL N. NELSON, A.M., M.D.,
OF BOSTON, MASS.

Concerning the origin of diphtheria much discussion has arisen. Although its infective character has been doubted by some, it is now quite universally accepted; and I shall confine my remarks to a brief review and discussion of the etiology of the disease from the standpoint of the biologist.

I shall adhere to the classification of microorganisms that is now universally adopted, viz., using the term "bacteria" in a generic sense, including both the

Micrococci, the ball forms and the
Bacilli, the rod forms.

That bacteria were early found in diphtheritic membrane, even before the recent improvement and perfection of the microscope permitted the researches and investigations resulting in the discovery of many pathogenic microorganisms, is not to be wondered at, when we realize that the healthy human mouth is constantly infested with bacteria of various kinds; not less than thirty different varieties having been isolated and cultivated by my friend Prof. W. D. Miller, whose labors have won for him the distinction of being the only American who has been honored with a professorship in the University of Berlin. We

must remember, however, that it is one thing to prove the existence of microorganisms in a diphtheritic false membrane, and another thing to prove that these germs are the *cause of the disease*. The difficulties are very great, and in the case of diphtheria as perhaps in no other disease, do we realize the importance of the isolation of the bacteria and their cultivation in a pure state, together with the reproduction of the disease by inoculation of the cultivated germs; before an attempt can be made to judge whether they are present as the cause of the disease, or are there, as most of them undoubtedly are, only as a result of the diseased state affording favorable conditions and soil for their growth and development.

The first reference to the idea that diphtheria is of parasitic origin, that I have found, is an article by Prof. Lacock,¹ and the idea was afterwards revived by Jodin.²

Oertel³ says concerning bacteria in diphtheria: "They were discovered as far back as 1868, by Buhl, Hueter, and myself (I called them at that time micrococcus) in false membranes, the blood, and the tissues; in like manner they were demonstrated by von Recklinghausen, Nassiloff, Waldeyer, Klebs, Eberth, Heiberg and others in the most different organs and tissues. In secondary infection of wounds, tracheotomy incisions, and ulcers, the grayish skin-like false membranes, as well as the tissues themselves, are crowded with these organisms."

In a "Treatise on Diphtheria," 1880, Dr. A. Jacobi reminds us that "Buhl was the first to discover schizomycetæ in diphtheritic membrane, but expressed no opinion as to the part they played in the process." Hüter found them in the gray diphtheritic covering of wounds, in the surrounding apparently healthy tissues, and in the blood. Hüter and Tomasi found them in the diphtheritic membranes of the pharynx and larynx, inoculated them on the mucous membranes of animals, and described them as small, round or oval, dark-colored, active little bodies. The latter observers look upon these organisms as a part of the infectious element. Oertel found them in diphtheritic membrane and in inflamed mucous membranes, in the lymphatic vessels, lymphatic glands, kidneys and other organs; he considers them at the bottom of the diphtheritic process and constituting the contagious element.

Nassiloff, too, after inoculation in the cornea, noticed an enormous multiplication of the microscopic organisms, and their appearance with pus-cells in the lacteals, and in the lymphatics of the palate, and even in the bones and cartilages. He asserts that the development of organisms is the primary step in the diphtheritic process.

Eberth made successful inoculations in living tissues: the microorganisms, introduced into the cornea, proliferated actively and caused an inflammation of irritative character, in the surrounding tissue. He asserts⁴ that diphtheria cannot occur without bacteria. Klebs inoculated the micrococci in pigeons and dogs and demonstrated the presence thereof in the blood of the animals after death. Orth found them in the pleura, lungs, kidneys, and urinary bladder."

Giacchi⁵ believes that a parasite is as necessary in the pathogenesis of diphtheria as the *Oidium vitis* is in the production of the disease of the grape.

Letzerich⁶ also differs from other German observers in regarding a true fungus, *Zygodemus fuscus* as the specific contagion of diphtheria.

The *Micrococcus diphtheriae* Oertel⁷ is thus described: "It has an oval form with a length of 1 to 1.5 μ , and a breadth of 0.3 μ ; larger individuals, found nearer the surface, being 4.2 μ long, and 1.1 μ broad. Where the individuals are more scattered, they occur mostly in pairs, rarely a number connected into a torula-like chain. When present in masses, the cells lie so close together that it is difficult to determine whether they are connected or not. They are then imbedded in a gelatinous envelop, and thus combined in masses into a colony."

Talamon⁸ does not recognize the *Zygodemus fuscus* of Letzerich nor the *Mycrosporon* of Klebs, as the cause of diphtheria, which he believes to be a mycelium with characteristic growths from 2 to 4 or 5 μ size, and having two kinds of spores:

a. Round or oval spores, which are the spores of germination, which occur in zooglea, and

b. Rectangular spores, which represent the third term of development of the fungus. These he has cultivated and inoculated on the mucous membrane of the mouth and nose of six rabbits, two guinea pigs, four frogs, one cock, and four pigeons, with reproduction of the membrane and death of some of the animals.

Klebs⁹ mentions that at first he supposed there was only one form of microorganism present in diphtheria. This he called the *Microsporon diphtheriticum*, and he claimed that it produced both rods and cocci, as different forms in the development of the same organism. Afterwards, however, he says he recognized another form of diphtheria, which was characterised by the presence of bacilli. The latter form he found at Zurich. It corresponded with the first form only in the gross anatomical changes. The latter

form is characterized by the tendency to an extremely rapid extension of the membrane into the trachea, even while the affection in the pharynx is still in active process. Death usually occurs from suffocation.

Morphologically Klebs says that the bacilli are long and narrow, and that they hardly attain the size of the bacillus tuberculosis. Two spores are always found in each rod. When the diphtheritic membrane is dried gradually over sulphuric acid at the ordinary temperature, the spores increase very rapidly, and then rods may be found which contain no spores, while others contain four spores. He is convinced, he says, that a true diphtheria exists only when rod-shaped organisms are present in the membrane. This allows of two possibilities; in the microspore form we have micrococci, together with somewhat long rods which do not contain spores, and in these cases a general infection is rapidly developed. In the bacillus form, on the contrary, which is first dangerous on account of its rapid extension on the mucous membranes, we find a great number of small rods which contain from two to four spores.

We learn from the address of Dr. E. G. Barnes¹⁰ that Loeffler, whose investigations were extensive and are published by the New Sydenham Society, found, in the cases he examined, two organisms present in large numbers; the one were chain-forming micrococci or streptococci; the other the bacilli described by Klebs as characteristic of diphtheria. The streptococci may be exonerated from being the active cause of diphtheria by the fact that they are present in various other diseases which are accompanied by lesions of the mucous membrane; for example, small-pox, typhoid and puerperal fever, and therefore may be regarded as accidental; that they are found only in a limited number of cases of human diphtheria, and that, when inoculated on lower animals, they never produced a disease even resembling it. Much stronger evidence was shown by Loeffler in favor of Klebs' bacillus being the true cause, and he even produced a similar disease by inoculating them on lower animals; but, on the other hand, he found they were not present in a number of undoubted cases of diphtheria; that in the false membrane he produced by introducing them through a wound in the trachea in rabbits and fowls, he did not find them in the same typical arrangement as in man; that they produced no effect in several animals otherwise susceptible to their action when applied to the uninjured mucous membrane of the fauces, respiratory passages, eyes and vagina; that paralytic symptoms did not occur in the inoculated animals; and, lastly, that in one case he found a perfectly indistinguishable bacterium in the saliva of a healthy child.

Many allusions are now being made in the secular press to the work recently done in Pasteur's laboratory, which has been described in the *Gazette Hebdomadaire de Med. et de Chir.*, January 18, 1889. MM. Roux and Yersin constantly found the bacillus of Klebs and Loeffler, which they describe to be a little thicker than the bacillus tuberculosis and of the same length. This description, you will observe, differs a little from the original description of Klebs quoted above. They have cultivated the bacillus, and their inoculation experiments have produced paralysis, without which they do not consider the proof of real diphtheria conclusive.

My own experiments in the cultivation and inoculation of the bacteria of diphtheria were made several years ago, and are reported in a paper read before the meeting of the Eighth International Medical Congress at Copenhagen in 1884.¹¹

In November, 1883, I assisted Dr. H. O. Marcy in performing the operation of tracheotomy upon a child 3 years old, who was suffering from a severe attack of diphtheria. He was *in extremis* at the time of the operation, the breathing being very short and difficult. Membrane covered both tonsils. The operation was successfully performed and a tube inserted, when the breathing became perfectly free. Previous to the introduction of the tube, a complete membranous cast of the trachea was removed through the opening. The subsequent history was unfavorable, for the child died of blood poisoning about thirty-six hours later.

Soon after the operation I inoculated one of my culture bulbs with a small piece of the membrane removed from the trachea. These bulbs are made after those of Sternberg, of the United States Army, which I then preferred to the method of culture on solid culture-media; I had not become thoroughly familiar with the latter method until some months later in Berlin, when I was soon convinced that it affords many advantages that cannot be obtained from cultures in bulbs. These bulbs are made from ordinary glass-tubing about three-tenths of an inch in diameter. In one end a bulb is blown, and the other extremity is drawn to a fine capillary point. These I made myself in quite large quantities at a time. They were filled two-thirds full with a sterilized beef-bouillon, then hermetically sealed, and in this condition they will keep indefinitely if successfully made.

For cultures I found it best to use bulbs which had stood the test of a temperature of 70° to 100° F. for several weeks; for if they remain clear and pellucid at the end of this time, any subsequent changes that might occur are due to the substances introduced.

Four days after the introduction of the diphtheritic membrane as seed, the liquid in the culture bulb kept at temperature of 70° became cloudy or turbid, and when examined with the microscope at 1,000 diameters, there were found immense quantities of a micrococcus, identical with those seen in the fresh membrane. This micrococcus has about the diameter of the micrococcus of pus, and is very slightly elongated. They were grouped in clusters of a few members each and belong to the group of staphylococci.

A second culture bulb was inoculated with a fraction of a drop of the liquid in the first, and three days later the same cloudy appearance was noticed, and examination showed identical micrococci. In this way the cultures were carried through ten generations, in each case several bulbs being inoculated at a time, and each one breeding true in three days. In all, about fifty bulbs were used.

My subsequent experiments of inoculation were carried on with the advice and assistance of Dr. Wm. F. Whitney. Four guinea pigs were inoculated in the cornea with the contents of one of the bulbs containing the culture of the sixth generation. One of these animals died thirty-six hours later of blood poisoning. The others became very ill, losing their appetite and the eyelids becoming much swollen and oedematous, with profuse discharge which contained the micrococci. The cornea became cloudy and was covered with a membrane. Two of these animals were killed on the third day after inoculation, this being the period at which the micrococci developed; one was allowed to get well, but the eyes were completely destroyed.

In the aqueous humor of the eyes dissected there were found micrococci, which were also found in sections of the cornea of the eyes, which had been placed in alcohol immediately after removal, and when hardened were cut with a microtome.

These experiments are limited in number and, I know, need further confirmation; but as far as they go they seem to show that there is a micrococcus of diphtheria which can be cultivated, and which when inoculated in the guinea pig produces diphtheria.

If, however, further proof is needed I can give it; for on the third day after killing the animals, and after no other exposure, I myself became ill, developing a severe attack of diphtheria, which appeared first in one tonsil and the uvula, and then on the other tonsil, being accompanied with severe constitutional symptoms and followed by a slow and tedious recovery. This has proved, to my satisfaction, at least, the correctness of these views.

Thus we see in brief review the chain of the sequence of events:

A typical case of diphtheria in a child;

¹¹ *Compte-rendu de Congrès Périodique International des Sciences Médicales*, 8me session, Copenhagen, 1884, t. i. Section de Pathologie Général et d'Anatomie Pathologique, p. 114.

The presence of micrococci in the membrane;
The cultivation of the micrococci in pure cultures to the tenth generation;

The inoculation of guinea pigs with micrococci of the sixth cultivated generation, and reproduction of the disease;

The unwitting inoculation of the experimenter, thus bringing the disease back to its original form in a human being.

PHTHISIS PNEUMONICA ET LARYNGITIS CHRONICA.

*Read before the Medical Society of the District of Columbia,
December 12, 1888.*

BY A. A. HOEHLING,
MEDICAL INSPECTOR, U. S. NAVY.

C. H., Corporal U. S. Marine Corps, native of Wilmington, Del., age, 41 yrs. 8 mos., enlisted at Annapolis, Md., August 14, 1887. Admitted from U. S. Naval Academy, Annapolis, Md., at 2:30 P.M., September 19, 1888. Died November 21, 1888.

"The patient has had sixteen years' service in the U. S. Marine Corps. Dates the beginning of his ill-health in September, 1887, when he 'caught cold' sleeping on deck on board the U. S. S. 'Dolphin' on a passage from Annapolis to Philadelphia. He has been from time to time under treatment at this station, but has continued on duty until two days ago. He has in the last twelve months had fever from time to time, night sweats, cough and progressive emaciation, with loss of appetite. He has percussion dulness at tops of both lungs, irregular expiratory blow and subcrepitant râles, most abundant on right side in front. He has had occasional hoarseness for six or eight months. This has grown rapidly worse in last ten days, with irritation of larynx, hoarseness of voice almost to extinction, and much difficulty and pain in deglutition. Epiglottitis is thickened and distorted, and left aryteno-epiglottidean fold swollen, and encroaching upon cavity of larynx to such an extent as to obstruct view of vocal cords. Patient has had cod-liver oil since September 1. Last two days spraying of larynx once a day with sol. nitr. silver, gr. v to 3j, also three times a day with a 2 per cent. sol. cocaine before eating."

At present he has the characteristic appearance of a consumptive, is considerably emaciated, cannot speak above a whisper, and swallows liquids with much difficulty; He has bronchial breathing at the apex of both lungs, and below this, especially on right side, subcrepitant râles take the place of the normal vesicular murmur. Laryngoscopic examination reveals an cedematous and congested state of aryteno-epiglottidean folds and the epiglottis much thickened, interfering with deglutition. Ordered diet of milk, eggs, rare beef and corn-starch. To have ol. morrhue and

whisky, and to use steam atomizer with wine of ipecac.

September 23. Morning temperature has been normal and evening temperature has been about 101° daily. Expectoration profuse. Cough harassing, and breathing labored on account of condition of throat; deglutition somewhat improved. Treatment continued, to use also ammon. hydrochlor. sol. in atomizer.

September 27. Condition slightly improved. Continue treatment.

October 3. Patient states he has gained 8 lbs. since admission to hospital. Laryngeal symptoms remain unchanged; less expectoration. Temperature range A.M. normal, P.M. about 100.4°. Is taking ol. morrhue and beer. Is using a spray of tr. ferr. chlor., alternating with a spray of vin. ipecac.

October 10. Condition continues about the same. Throat sprayed twice daily with Dobell's solution and sol. cocaine, followed by application of equal parts of tr. iron and glycerine. Deglutition seems improved. Continue treatment.

October 20. Evening rise of temperature less, about 99.6°. General treatment continued. Is losing in weight and strength.

October 27. Patient is gradually failing. No ulcers apparent in throat yet. Continue general treatment.

November 6. Patient very weak. Expectoration profuse, cough harassing, deglutition much impaired, but the patient is very hopeful. Ulceration of the cords apparent, though a good view cannot be had. Continue treatment.

November 12. Patient is failing slowly, is now confined to bed. There is apparently a large cavity in right lung and left lung seems much involved; cough harassing, expectoration profuse. Supported by milk-punches. Swallows with difficulty. Treatment continued.

November 16. Scarcely able to swallow anything; very weak, failing slowly.

November 17. Very weak. Refuses to take nourishment by mouth. Ordered enemata of beef-tea and whisky every three hours.

November 19. Very weak; supported by enemata of egg-nogg, beef-tea, milk, etc.

November 20. No change.

November 21. Died at 2:25 P.M.

Necropsy twenty hours after death. Body greatly emaciated; rigor mortis passing off. Upon opening the thorax the pleura was found firmly adherent to the chest wall and diaphragm (entirely obliterating the pleural cavity), requiring considerable force for its detachment.

Pericardium contained about 60 cc. of clear serous fluid.

Heart normal. The cavities contained each a small amount of dark blood clots, and large fibrinous clots extended from them several inches into the large vascular trunks.

Lungs were studded with miliary tubercle, increasing in quantity from apex to base; on section the tissue seemed exsanguine, of a grayish color, dotted with the black tubercle and filled with numerous cavities, varying in size from a pin to a small orange, containing offensive pus, with the exception of a small portion at base of each lung which was highly congested, with tubercle throughout its substance. All the smaller bronchial branches were obliterated by the tubercular deposit in the surrounding portion of the tissue. Fibrinous bands were found between the lobes and the larger cavities were lined by a similar membrane.

Larynx.—The upper part of posterior portion of the thyroid, the arytenoid, the epiglottis, and the ligaments and attachments corresponding to these, with the vocal cords, were destroyed by ulceration.

Abdominal viscera not examined, and cranium not opened, as it was deemed unnecessary.

NOTES ON TWENTY-SEVEN CASES OF DIPHTHERIA,

OCCURRING BETWEEN JULY 1, 1888, AND JANUARY 1, 1889.

Read before the Section for Clinical Medicine, Pathology and Hygiene, of the Suffolk District Medical Society, January 19, 1889.

BY HENRY JACKSON, M.D.,
OF BOSTON.

From July 1, 1888, to January 1, 1889, I treated twenty-seven cases of diphtheria out of 1,031 cases of all kinds, seen in the second district of the Boston Dispensary, situated on the West side of Hanover street. Of these cases, five died; four of septicæmia, one of laryngeal obstruction.

Five cases were very mild; two were not confined to the bed.

In most of the cases the membrane was confined to the uvula and pillars of the pharynx. In these cases a large part of the roof of the mouth and lips was covered with membrane. Fifteen cases occurred in houses where the sanitary condition was bad. Ten case where the sanitary condition was apparently good. Two cases in a house that seems to be in good condition, and yet one where I have found much sickness in the last two years, notably diphtheria last winter.

Where there were several children in a family, usually one or more cases of diphtheria appeared shortly after the first cases. Namely:

In a family of three children all had the disease.

In a family of five children four had the disease.

In a family of three children two had the disease; later in the year two members of this family had typhoid fever. In all cases the disease was strictly confined to the house where it first appeared, and in only one instance did the disease

spread to other families living in the same tenement.

Of the twenty-seven cases four were young adults; the average age of the children was 5 years, the youngest being 18 months.

As of importance in making an early differential diagnosis between diphtheria and follicular tonsillitis, I have found that in diphtheria:

1. The temperature was much lower, often normal.

2. The constitutional symptoms were usually less severe at first.

3. The glands about the neck were more swollen and tender.

In all cases I have felt justified in making a diagnosis of diphtheria where there was membrane on the uvula or on the pillars of the pharynx.

As last year I could report that, having had in my charge in this district a large epidemic of scarlet fever, I was not aware of having carried the disease to a single child, so this year not a case of diphtheria has occurred in a family that was under my care for other diseases.

In other words, so far as an opinion can be formulated from so small a number of cases, the disease is very infectious to young children brought in immediate contact with those sick; the disease does not spread from house to house; the disease is not easily carried by a third person.

The following list shows the character and distribution of the various infectious diseases in the portion of the city above described, during like periods of two successive years.

JULY, 1887, TO JANUARY, 1888.

Diphtheria	8
Tonsillitis	57
Scarlet fever	68
Measles	5
Typhoid	24

JULY, 1888, TO JANUARY, 1889.

Diphtheria	27
Tonsillitis	33
Measles	5
Scarlet fever	1
Typhoid	23

MEDICAL PROGRESS.

NERVE-GRAFTING.—At the meeting of the Clinical Society of London, on January 25, MR. MAYO ROBSON showed a girl, æt. 14, on whom he had successfully grafted two inches and a half of the posterior tibial nerve into a corresponding gap in the median nerve in the forearm. He also showed the tumor which had involved the median nerve, and had necessitated its removal. The history of the case, briefly, was that the patient had noticed the tumor growing for six years, but that it had grown more rapidly during the past twelve months, during which time it had

caused considerable inconvenience as well as deformity. The tumor, about the size of hen's egg, extended from the annular ligament in front of the right wrist up the forearm for about three inches, reaching laterally from side to side, the skin being firmly stretched over, but not adherent to the tumor, which appeared to be solid or semi-solid. On making an incision over the swelling the tumor bulged through the wound, and was easily separated from its cellular bed, leaving the mass attached above and below to a cord, which appeared to be inseparably blended with it. The attachments had therefore to be cut through. A microscopic examination showed that the cord was composed of nerve tissue, and on the patient recovering from the anæsthetic the parts in the hand supplied by the median nerve were found to be devoid of sensation. Arrangements were made by Mr. Robson to graft the sciatic nerve of a rabbit into the gap of the median nerve, but fortunately his colleague, Mr. Ward, kindly allowed him to arrange his operation at the same time that he was amputating a thigh, and to utilize the posterior tibial nerve, which was taken straight from the amputated leg into the prepared forearm, the transfer from one theatre to the other being made in a warm carbolic solution. Two inches and a half of nerve were utilized, the ends being attached to the proximal and distal portions of the median with a fine catgut suture, without the slightest tension either on the stitches or the nerve; the wound was well washed out with perchloride of mercury lotion and carefully sutured. Healing occurred by first intention. The grafting was performed forty-eight hours after the tumor had been removed, and thirty-six hours after the nerve had been grafted, sensation had so far returned in the parts supplied by the median that the touch of a pencil could be localized. Day by day sensation became more and more distinct, until when shown to the members of the Leeds and West Riding Medico-Chirurgical Society, five weeks after the operation, it was so perfect that the slightest touch could be localized, and although there was manifest diminution in volume of the abductor and flexor brevis pollicis, they were not completely paralyzed. Mr. Mayo Robson, after relating experiments on animals, which went to prove that reunion and even regeneration of nerves might occur, remarked that in such cases, where there had been absolute loss of nerve, return of function did not occur. He thought the case he had related presented very important physiological and clinical features: physiological, in that the living nerve must have immediately united and taken on function, so that thirty-six hours afterwards the distal portions of the median were functionally active; clinical, in that, if nerve grafting to such an extent could be certainly relied on, many hitherto hopeless cases may be

cured—for instance, in injury of an extremity with destruction of one or more chief nerve trunks, in the case of a tumor involving nerves, in paralysis due to cicatricial destruction of nerve, and in many other cases. He ventured to hope that, if, as in this case, two inches and a half of nerve would live, further experiments might show that greater lengths might survive; or if such were found to be impossible, that the grafting might be done piece by piece as in the case of bone grafting. The condition which he advised to be observed in such operations were: first, entire absence of tension in the grafted nerve—*e.g.*, two inches and a half being employed to fill an interval of two inches and a quarter; secondly, great care in dissecting out and handling the nerve; thirdly, immediate transference of the living tissue into its new bed; fourthly, the employment of only a single suture to fix the ends of the nerves; and fifthly, strict asepsis. He thought that this case, if he had correctly interpreted it, went to disprove the theory that a primary union of the divided ends of a nerve is only an appearance of union, and not a physiological one, and that the distal ends must pass through a process of degeneration before regeneration. He remarked that the return of function in the motor portion of the nerve was more gradual than in the sensory, and made suggestions which he thought might explain the difference. MR. BRYANT asked whether the suture had included the whole thickness of the nerve. MR. BOWLBY observed that the case seemed likely to prove a successful one, but at present it was not entirely so. It was the first recorded case of nerve grafting in this country, although a number of experiments and operations had been published on the Continent. This was the first case of primary grafting of a nerve—that was, within forty-eight hours of the injury. He pointed out that in a certain number of instances there had been restoration without re-establishment of continuity of the nerve. He had quoted several instances of the kind in his lectures at the College of Surgeons.¹ Still, on examining that particular patient, he found more sensation than he had ever seen before under similar circumstances. The condition of the muscles was not quite healthy, but still satisfactory. He mentioned as a curious fact that the power of voluntary motion often returned long before there was any reaction to electricity. He had remarked a bulla on the tip of the patient's index finger, which seemed to point to a trophic lesion. He questioned the accuracy of the view generally held, that after primary suture of the two ends of a divided nerve the lower end necessarily underwent degeneration. In a case in which he had brought the ends together, although fully an inch had been cut out, complete restoration of function ensued in a few days. In another case in which

¹ Vide the Lancet, Vol. ii, 1887.

union by primary intention took place, although there was no paralysis, yet for a long time there was no reaction to electricity. He also pointed out that sensation was a very vague term, and might exist in very varying degrees. Mr. Robson's patient still experienced numbness and tingling in the fingers, showing that sensation, if good, was not perfect. MR. BLAND SUTTON urged that it did not follow, because restoration of function had taken place after joining the cut ends of the nerve by means of a piece of the posterior nerve, that the latter had become incorporated with the median nerve. In experiments that had been carried out on animals it seemed that anything which acted as a conductor, so to speak, along which the reparative material passed, bits of chicken bone, catgut, etc., had been found to answer the purpose. The bullæ which had been noticed generally took some time to form, and he suggested that the patient was now getting the symptoms which would have followed had the grafting not been effected. He hoped that the future progress of the case would be carefully watched, and the additional information added to the report when published in the Transactions. THE PRESIDENT mentioned the case of a man from whom, in the course of an operation for the removal of a tumor, he had accidentally removed a large piece of the external popliteal nerve—too much, in fact, to admit of the ends being brought together. Loss of sensation and muscular degeneration followed in the parts supplied by the nerve, and the patient left the hospital in a rather unsatisfactory condition as regarded the leg. Some months later he looked the patient up, and found to his surprise that function had been restored, and the patient said he was as strong in the leg as ever he was. MR. MAYO ROBSON, in reply, admitted that the case was not yet an unqualified success, but its progress had been so uninterruptedly satisfactory that he quite anticipated it would ultimately become so. He had passed a very fine catgut suture through the whole thickness of the nerve. He observed that even if the piece of the posterior nerve had not become incorporated with the median nerve, yet, in view of the successful issue of the case, most persons would be inclined to commend the course that had been adopted.—*Lancet*, Feb. 2, 1889.

HYDROXYLAMIN IN SKIN DISEASES.—DR. EICHOFF, of the Municipal Hospital, Elberfeld, has found an admirable substitute for pyrogallie acid, chrysarobin, and other powerful reducing agents used in external applications for skin diseases in hydroxylamin, which is, chemically speaking, an ammonia in which one of the atoms of H is replaced by HO. The most suitable compound for dermatological use is the chloride, the formula of which is $\text{NH}_2\text{OH}.\text{Cl}$. This occurs in colorless,

strongly hygroscopic crystals, which are readily soluble in water, glycerine, or spirit, the solution showing an acid reaction. When introduced into the blood, hydroxylamin forms methæmoglobin, the blood rapidly becoming of a deep-brown color. In large doses—that is to say, 0.01 gram per kilogram of body weight—it produces hematuria in consequence of the destruction of the red corpuscles. It also acts on the nervous centres, producing narcosis. The high reducing power possessed by hydroxylamin renders it a powerful poison to low organic forms, and on this account it is to be very strongly recommended in dermatology. The preparation used by Dr. Eichhoff is the hydrochlorate dissolved in a mixture of equal parts of glycerine and spirits of wine in the proportion of 1 per 1,000. This is applied with a brush to the affected parts of the skin, which must first be carefully washed with soap three to five times a day. In this way he has treated five cases of lupus, five of ringworm, and one of parasitic syphilis, with excellent results. These were specially remarkable in two cases of very severe lupus. Dr. Eichhoff is hopeful that this remedy, which may sometimes perhaps be applied in the form of subcutaneous injections, may be found useful in psoriasis, parasitic eczema, and even in lepra and syphilis. He, however, warns those who propose to try it that it is a very powerful irritant, and that even for outward application a strength of 1 per 1,000 is quite enough.—*The Lancet*, February 9, 1889.

ACTION OF PARALDEHYDE.—DR. JOHN GORDON, of Aberdeen, after an extensive series of experiments and observations in regard to paraldehyde, summarizes his results as follows:

1. Paraldehyde caused an increase in the excretion of urea.
2. It did not in any marked way affect the quantities of chlorides excreted.
3. It did not invariably increase the excretion of the fluid constituents of urine, but in the majority of cases which I have recorded it diminished them.
4. The odor of paraldehyde, when given in large doses, was found in the urine, showing that some of it probably passed unchanged through the system.
5. After the full dose of the drug the respirations were slowed, and rendered tranquil and steady.
6. It had no appreciable effect on temperature.
7. In cases of average health without sleeplessness it did not have any hypnotic influence except in large doses.
8. It caused no loss of appetite.
9. There was sometimes a tendency to perspiration under its influence, which atropine controlled.
10. The blood-pressure was only slightly reduced by the smaller doses, the larger dose reducing it more, but only after distinct slowing of the respiration.
11. The pulse was slowed.
12. It diminished the reflex excitability of the spinal cord.
13. It had a peripheral influence in controlling sensation.
14. It speed-

ily diminished, and in large doses destroyed, the irritability of motor nerves. 15. Equal doses diminished the excitability of motor nerves sooner than that of muscle. 16. Small doses first slightly excited and then diminished the excitability of muscle substance. 17. Large doses speedily destroyed (temporarily) the irritability of muscle substance. 18. There was a tendency to complete recovery in the muscle after a small dose, but seldom complete recovery after a large dose. 19. Curarized muscle showed increased excitability over non-curarized muscle when treated with an equal dose of paraldehyde and equally stimulated.—*British Medical Journal*, March 9, 1889.

CHLOROFORM IN DYSPEPSIA.—Chloroform administered in the various forms of dyspepsia overcomes fermentation and flatulence; it is best given in one of the following formulas:

1. *Method of DR. WILS.*—From ten to twenty drops of chloroform, to be taken in a few spoonfuls of sweetened water, in flatulent dyspepsia. After a few minutes eructations occur, followed by improvement.

2. *Method of DR. HUCHARD.*—Administer before each meal one dessertspoonful of the following:

R. Chloroform water	150 parts.
Mint water	30 "
Water	120 "
℞.	

Or, from eight to ten drops of the following mixture in a wineglass of water:

R. Tincture of nuc. vomica	} āā ʒj.
Tincture of gentian	
Tincture of anise	
Chloroform	gtt. xx-xl.
℞.	

An appropriate diet and oxygenated waters at meal-times form part of this treatment.

3. *Methods of DRS. REGNAULT and LASÈQUE.*—This treatment applies particularly to painful dyspepsias with dilatation of the stomach:

R. Chloroform water	150 parts.
Orange-flower water	50 "
Water	100 "
℞.	

One dessertspoonful to be taken, at intervals of fifteen minutes, until the pain ceases.

Or the following for the same affections:

R. Chloroform water	150 parts.
Tincture of anise	5 "
Water	145 "
℞.	

—*Revue gén. de Clin. et de Thérap.*, Feb. 28, 1889.

ANTIPIRYN IN LABOR.—DR. ERMANNO PINZANI recently made a communication to the Società Medico-Chirurgica di Bologna,¹ in which he gave an account of some experiments he had made with the view of ascertaining the effect of antipyrin on the strength of the uterine contrac-

tions in labor. Two series of experiments were made. In five cases he simply kept his hand on the woman's abdomen for some hours, and noted the condition of the uterus before and after the administration of the drug. In eight other cases (on which he made in all twenty-three experiments) he passed an India-rubber ball, first disinfected, and then filled with a watery solution of corrosive sublimate, into the uterus; this he connected with a manometer, which gave him an accurate gauge of the pressure exerted by uterine contractions on the fluid in the ball. Dr. Pinzani was careful to exclude irritation of the uterus by the foreign body as a source of fallacy by previously warming the fluid in the ball to the temperature of the body, and by waiting for some time after its introduction before making observations. In the first set of experiments, 3-gram doses of antipyrin were given by the mouth; in the second, the doses were from 1 to 2 grams. Dr. Pinzani came to the conclusion that antipyrin relieves the pains of labor simply by lessening the force of the uterine contractions. The effect of the drug showed itself in about two hours after hypodermic injection, and four or five after administration by the mouth. He noticed that infants suckled by women who had had antipyrin given them during labor were apt to suffer from diarrhoea. Dr. Pinzani's verdict is, therefore, decidedly against the use of antipyrin in midwifery practice.—*British Medical Journal*, March 9, 1889.

IGNIPUNCTURE OF THE TONSILS.—DR. WILHELM ROTH, of Fluntern, finds that in order to reduce the size of the tonsils without risk of troublesome hæmorrhage, which is not uncommon, especially in young subjects, the best plan is to employ ignipuncture, as has been recommended by Krishaber, and more recently by Verneuil. The tonsils and neighboring parts are first brushed over with a 10 to 20 per cent. solution of cocaine. The finest point of the thermocautery, heated to redness, is then inserted to a depth of about five millimetres in three or four spots a few millimetres apart from one another on the tonsils. The instrument is not allowed to remain more than one or two seconds in the tissue. The whole operation, including both tonsils, can be performed in a very few minutes without any bleeding, and with scarcely any pain. It must be repeated four or five times at intervals of two or three days, and this is usually sufficient to cause the tonsils to return to their ordinary condition.—*Lancet*, Feb. 16, 1889.

TREATMENT OF INGROWING TOE-NAIL.—DR. THEODOR CLEMENS, of Frankfort, strongly recommends the employment of tin-foil in the treatment of ingrowing toe-nail. He first has the toe thoroughly washed with soap and carefully dried. He then envelops the whole nail with

¹ Gazzetta degli Ospitali, February 10, 1889.

tinfoil, putting a strip between the portion that grows in, and the raw surface caused by it. The tinfoil is fixed by means of a very thin layer of common wax, and the patient told not to wash the part, but to use dry bran for rubbing off the dirt. Of course the toe has to be repeatedly dressed with tinfoil, but, if the operation is carefully performed, it is surprising how long the tinfoil will remain intact; even when the patient is, as was usually the case in Dr. Clemens' hospital practice, very poor and very badly shod. The results are stated to have been most satisfactory, and are ascribed by Dr. Clemens not merely to the mechanical action of the tinfoil, but to the effect of the permanent contact of a combination of metals comprising iron, copper, arsenic, molybdenum, wolfram, and bismuth, with a moist and growing portion of flesh. This, he says, brings about in a few weeks the complete healing of the sore, and causes the nail to grow more slowly, and in a more healthy manner.—*Lancet*, Feb. 16, 1889.

TREATMENT OF VALVULAR DISEASES OF THE HEART.—DR. DA COSTA in the course of a valuable and suggestive paper says: "From adonidine I have witnessed, in $\frac{1}{10}$ to $\frac{1}{5}$ grain doses three times a day, some admirable results; but more in cases of functional than of valvular diseases of the heart. Yet even here I have known it to act as an excellent heart regulator." Chloride of barium he finds both a general and a cardiac tonic, a remedy that increases the tone in the blood-vessels, a fairly good diuretic, and one that can be taken for a long time without disordering the stomach. He usually gives it in doses of $\frac{1}{10}$ grain three or four times daily; overdoses are apt to produce diarrhoea. It seems also to lessen cardiac pain." He finally says: "I must not bring this paper to a conclusion without mentioning a point of which I know the great value—to make periodical examinations of persons affected with valvular disease. I am not speaking of those in whom serious symptoms call for constant supervision; rather of those who, under our advice, take little or no medicine. In them, too, it is true that the heart of to-day may not be the heart of a month hence. Yet they are the ones chiefly in whom beginning changes can be most readily met, and whose lives, with the aid of treatment when necessary, can be greatly prolonged. Let them be made aware of the importance of skilled supervision. It will not mean needless interference; it will mean judgment as to when interference is really helpful.—*Amer. Journal of the Med. Sciences*, November, 1888.

NEW OPERATION FOR EMPYEMA.—PROFESSOR M. S. SUBBOTIN, of Kharkoff, describes in *Trach* (No. 45) a new operation he has devised for opening the thoracic cavity in empyema, with the

view of obviating the dangers arising in Estlander's operation and in the modifications of it practiced by Schede and Sprengel from the extensive raw surface which is necessarily allowed to remain in contact with the purulent discharge. The patient having been chloroformed, an incision was made along the seventh rib, which was then stripped of its periosteum and excised to the extent of 7 or 8 centimetres. An extensive opening was here made into the pleural cavity. After the pus had been evacuated the cavity was carefully cleansed and the opening well covered with gauze, and a gauze compress applied. An incision was then made along the border of the pectoralis major about 5 centimetres in length, exposing the sixth, fifth, and fourth ribs, and these were cut away (the periosteum not being left) with forceps until the rib became movable. Another incision was then made in the line of the posterior fold of the axilla, exposing the same ribs, which were again divided as before; the wounds were then sutured and dressed with gauze, a large thick pad of the same substance being applied outside, with a good compress bandage round the thorax. The upper wounds were kept from communication with the empyema. When after a few days the intrathoracic wound was dressed, a drainage tube was put in. The case recovered, but three months after the operation there was still a small sinus which continued to discharge. The advantages claimed by Professor Subbotin for his operation are the small raw surface which is left in contact with the purulent matter, and the firm but movable portion of the thoracic wall which can be pressed inward by bandaging, so as to diminish to a considerable extent the size of the cavity.—*Lancet*, Dec. 15, 1888.

NIGHT-TERROR AND SCREAMING IN A CHILD CURED BY REMOVAL OF THE TONSILS.—The patient, a boy, æt. 7, seemed to be quite well all day, but every night, after he had been asleep some little time, he used to wake up in a state of great terror. In a short time he got over the attacks, and would lie down to sleep again. He was examined, and nothing found except large hypertrophied tonsils. These were conjectured to be the cause of the symptoms. They were both removed. The child promptly got rid of his night-terror and screaming. It was presumed that in deep sleep, when he lay in some unfavorable position, the tonsils obstructed the respiration.—*The Lancet*, Oct. 6, 1888.

TREATMENT OF ERYSIPELAS.—DR. NOLTE reports that for several years he has had good results in the treatment of erysipelas with mucilage of acacia and carbolic acid (3 to 5 per cent.). The affected locality, and the adjacent skin, is painted over twice daily with the mixture, which is then allowed to dry.—*Therapeutische Monatsshefte*, January, 1889.

SATURDAY, APRIL 6, 1889.

THE UNION OF MEDICAL SCHOOL AND
UNIVERSITY.

Continuing the discussion of this subject, begun in THE JOURNAL of last week, it is proper to inquire as to the specific advantages belonging to the university system of medical education. In the first place, says Dr. Welch in his address, "this system may be expected to maintain the proper balance between purely technical training in the medical art and cultivation of the medical sciences upon which this training should be based, or to express the same idea perhaps more intelligibly. . . . between the practical and the scientific side of medicine." We would not give this particular advantage the first place, however. We should say, the *proper* union of medical schools with universities would insure that amount and degree of general education without which no one is fitted for the study of medicine. Under the term "general education" we would include *preliminary education for the study of medicine*. We believe the time will come, though our belief may be Utopian, when the medical schools will require as a condition of matriculation that each student shall have pursued a course of study looking to the study of medicine. The hope for this lies in the proper and true union of the medical school with the university; not a mere "affiliation," not a nominal connection, but an organic union.

The scientific branches of medicine receive too scant recognition and attention. "In a medical school permeated by the university spirit," says

Dr. Welch, "and in intimate association with a university, these sciences cannot fail to receive proper recognition." Without wishing to appear unnecessarily critical, we would add to "the university spirit" the scientific spirit, which could scarcely fail to be engendered by a proper preliminary course to the study of medicine. How much more willingly, and how much more rationally would the medical student pursue his courses of human anatomy and histology if he studied them in the light that he has gained by a study of comparative anatomy, embryology, and biology! How much more intelligently would he study physiology if he were a physicist and chemist. "Physiologists," says Du Bois-Reymond, "should regard themselves as chemists and physicists who work only in a particular direction." Pathology requires the light of biology, physics, and chemistry. In a word, as was pointed out by Dr. Gairdner in his Presidential address before the British Medical Association last year, and aptly illustrated by Dr. Clifford Allbutt in his address in medicine, the true physician must be and is a naturalist—a *Naturforscher*—and this no one can be who neglects the necessary educational basis of a naturalist. "Universities," says Dr. Welch, "have always kept alive the ideal that the interests of life are not wholly material, but that they are spiritual and intellectual as well. May the time never come when this ideal shall be replaced by the estimate of knowledge, solely for its commercial value, or its immediate application to the practical necessities of life. Somewhat of this true university spirit should pervade medical study, if the practice of medicine is to be a profession and not a trade or a handicraft."

Dr. Welch then goes on to speak of the scientific spirit that would be engendered in a university medical school of the character indicated. While it is not claimed that the desired results are possible only in a medical school in a university, it must be admitted that the atmosphere of a university is particularly favorable, and that of an independent medical school unfavorable for their attainment.

Few university men, or thinking men, will take issue with Dr. Welch in his opinion that the last two years of a medical course should be given mainly to the study of the practical branches of medicine; and this study should be more practical

and demonstrative than it is at present. In speaking thus the two-course schools are left out of consideration, as they should be out of existence. A shorter period of medical study than four years seems to Dr. Welch possible only with a preliminary medical training such as is already furnished with excellent results in some of our universities, and with a supplementary experience in a hospital.

Still another benefit to be derived from the proper union of medical school and university is the encouragement of research, which naturally follows the existence of the scientific spirit. With this spirit, and with well-equipped laboratories, workers will be abundant, the university will win renown, and medical science will make progress. There will be workers here, as in other countries, that seek the truth for its own sake, whenever and wherever it can be found, without regard to its immediate practical value. Medicine offers all the attractions and fascinations of a natural science; all that we need to make workers and to encourage research is the scientific spirit, and laboratory facilities. "When America does wake up to the necessity of these things," said a distinguished German physiologist, "then let Europe look to her laurels." America will wake up to the necessity of these things when the general public better understands the cost of sickness and the money-value of health.

A very practical advantage in making a medical school a department of a university is economy of organization. "A university provides for the study of certain subjects which either are included in a medical course, or should be required in a course preliminary to the study of medicine. The most important of these subjects are chemistry, physics, botany, zoology, and comparative anatomy." In the medical schools of this country chemistry is the only one of these sciences that has any place in the curriculum, and even this is an unsatisfactory feature, physiological chemistry being generally altogether ignored. As the matter now stands, organic and inorganic chemistry, which should be entirely acquired in the preliminary course, are the only branches of the science taught, in the medical schools.

ENLARGED TONSILS AND THORACIC DEFORMITY.

It is now a well-recognized fact that certain cases of hypertrophy of the tonsils are accompanied by a special deformity of the chest, at a point corresponding exactly with the union of the inferior and middle third of the chest-wall. This deformity, first noticed by Dupuytren, is the subject of an interesting paper by M. BILHAUT, in the *Annales d'Orthopédie et de Chirurgie pratiques*, No. 6, 1889. The deformity was at first attributed to rachitism. Further study of the subject, especially by Coulson, of London, and Mason Warren, of Boston, showed that there was more than one chest-deformity present in cases of hypertrophy of the tonsils. Two distinct classes were differentiated: in the first are placed the rachitic deviations in subjects of enlarged tonsils; the second class comprises those cases only in which the thoracic deformity is essentially due to tonsillar hypertrophy. It is the second class that M. Bilhaut discusses.

Lamberton not only described this deformity, but he differentiated the analogous lesions, and indicated the most rational treatment. "The ribs forming the median part of the thoracic walls are more or less depressed or sunken, so that these bony arches present an incurvation opposed to their natural curvature, and the maximum of this incurvation corresponds almost exactly to the middle points of the bones. As a rule, the upper part of the chest is not involved by the deformity, but retains its normal form, and, if it appears more convex, if the ribs appear to be more prominent, and more curved outward, it is, in most cases, due to the contrast between the natural curvature of the upper, and the unnatural depression of the median ribs. The condition of the sternum is in perfect accord with that of the costal walls; it is markedly sunken at the union of its middle and lower third, but for the remainder of its extent preserves almost exactly its normal form. The incurvation of its lower part gives the appearance, by contrast, of its upper part being much more prominent than normal." The existence of this deformity does not exclude those of a different nature, such as scoliosis, kyphosis, Pott's disease, etc., and one of these lesions may be found in a patient with the thoracic deformity due to tonsillar hypertrophy.

One of the most notable contributions to the

literature of this subject is a *Thèse* sustained before the Faculté de Médecine in 1881, by Dr. Gailard, of Chaton. This *Thèse* was the outcome of a most careful study of the etiology, symptomatology and treatment of this affection. He called special attention to the lateral flattening of the thorax and the projection of the sternum, giving the "pigeon breast." The difference between this alteration of the thorax and that due to rachitism is marked. In rickets the costo-sternal cartilages form a projection, and two *vertical* grooves extend from above downwards along the chest. The groove caused by tonsilar hypertrophy, however, is transverse, giving somewhat the appearance of a ligature having been maintained for a long time at the junction of the lower and middle third of the thorax. Alphonse Robart explains this deformity by a diminution of intrathoracic tension, the result, he claims, of impeded entrance of air. The narrowness of the upper air-passages impedes the entrance of air, while atmospheric pressure, being not compensated, causes the deformity of the flexible chest-walls of the young subjects. Billhaut regards this theory as indefensible, and is inclined to adopt that of Lambon, who says, in regard to Robart's theory that atmospheric pressure should act in the same manner on all points of the thorax, and not on a limited portion. Lambon attributes the deformity to forced diaphragmatic respiration; and as a matter of fact the line of deformity is the line of insertion of the diaphragm. Yet it may be asked why a similar deformity is not found in emphysematous and asthmatic persons?

The first thing to be done in the way of treatment is to remove the enlarged tonsils, partly or wholly. If the deformity is sufficiently marked to require orthopædic treatment, Billhaut advises corsets that exercise slight pressure on the broader portion of the chest. Sayre's plaster jacket may be used, says Billhaut, but preference should be given to a laced corset. At the point of greatest circumference a layer of wadding or soft-rubber cushions may be placed. In very young children a simple corset will be sufficient as a rule. Massage and frictions should be utilized. It is useless to begin any method of orthopædic treatment, however, until the hypertrophy of the tonsils has been reduced or removed.

EDITORIAL NOTES.

DR. JOHN SWINBURNE died at his residence in Albany, N. Y., on March 28, 1889, aged 69 years. He had long been one of the most eminent members of the profession in that city. He had, at different times, filled the offices of Health Officer of the Port of New York, Member of Congress, and Mayor of Albany.

DR. R. L. HOWARD, of Montreal, Canada, died on the 28th of March, 1889. He was Dean of the Faculty of Medicine in McGill University, and well known as a leading member of the profession.

COLCHICINE IN OCULAR THERAPEUTICS.—At the meeting of the Société d'Ophthalmologie of Paris on February 5, M. DARIER said that since the discovery of salicylate of soda many ocular affections have been regarded as of rheumatic nature, and have been much benefited by this agent. This drug has been shown to be of great efficacy in cases of marginal corneal ulcers of arthritic nature, in certain cases of iritis, and in simple episcleritis, however intense, so long as the sclerotic tissue is not seriously involved and the cornea is not infiltrated. In the cases of scleritis with corneal complication, as well as in certain grave forms of serous iritis and of anterior sclero-choroiditis, neither salicylate of soda in large doses, nor salicylate of lithium show any efficacy. But with colchicine in doses of 2 or 4 millig. a day, says Darier, excellent results are obtained. In persons of gouty and rheumatic history colchicine is of signal value, especially in chronic and severe cases in which salicylate of soda has no effect. A patient with simple episcleritis may be cured easily by the salicylate, but if there is scleritis, with sclerosing keratitis, 2 to 4 millig. of colchicine should be given with the salicylate. In patients with hereditary accidents, and in whom the scleritis is the first manifestation of the arthritic diathesis, colchicine may be advantageously combined with benzoate of soda or lithia, or with carbonate of lithia, says Darier, if the antecedents are unmistakably gouty. It appears, however, that urate of lithium would be much better than the carbonate, which is a very insoluble compound in the animal fluids. Colchicine may be prescribed in the form of granules of one millig. each. One, two, four, and even six may be taken in one day, the patient

being instructed to lessen the dose when symptoms of colic occur. But no preparation of colicum is well borne for any considerable length of time.

REVISION OF THE UNITED STATES PHARMACOPŒIA.—We desire to direct the attention of all parties interested in the proper revision of the Pharmacopœia for 1890, to the official call for the *General Convention* of revision, found under the head of miscellaneous notices in the present number of THE JOURNAL. The Convention is to assemble in Washington, D. C., at noon, May 7th, 1890. "Every incorporated medical or pharmacal college, association, or society desiring to be represented in the Convention," should send to Robert Amory, care of Dr. Edwin N. Brigham, 19 Boylston Place, Boston, Mass., its corporate title and a list of its officers. For further information see the call in another column.

THE BUFFALO COUNTY (NEB.) MEDICAL SOCIETY has been recently organized, with the following officers: Dr. G. L. Humphrey, President; Dr. J. J. Porter, Vice-President; Dr. F. H. Duckworth, Secretary.

NURSING INFANTS WITH ASSES' MILK.—The public charities of Paris, says the *Scientific American*, under the advice of the physicians have substituted for the milk of goats that of asses, and have installed an ample yard near the pavilion of the rickety and scrofulous children, which is separated only by a short covered passage-way. A very picturesque scene is the spectacle of the lactation of the infants in this enclosure every morning. The women that have charge of the animals hold the children in such position that they can suckle the docile animals, which they do with avidity. The administration d' Assistance Publique has calculated that one young ass is able to lactate abundantly for nine or ten months.

ASSOCIATION NEWS.

American Medical Association. Fortieth Annual Meeting.

To be held in Newport, R. I., June 25, 26, 27 and 28, 1889.

SECTION ON STATE MEDICINE.

The following additional papers have been an-

nounced for presentation to the Section on State Medicine at the forthcoming meeting of the Association:

"The Necessity for Sanitary Supervision of Schools," Dr. George H. Rohé, Baltimore, Md.

"The Purification of Drinking Water for Cities," Dr. Charles V. Chapin, Providence, R. I.

A Paper, by Dr. A. N. Bell, Brooklyn, N. Y.

It is requested that gentlemen who have promised papers for this Section and have not designated the titles thereof, will send the titles to the Secretary as soon as possible.

In order to systematize the work of the Section, it would be a favor to have the names of gentlemen that desire to discuss any of the papers to be read before the Section.

S. T. ARMSTRONG,

Secretary of Section on State Medicine.

U. S. Marine-Hospital Service, New York, N. Y.

SECTION ON LARYNGOLOGY AND OTOTOLOGY.

The Secretary of this Section has written to about 200 of the best known laryngologists and otologists in the country, a number of whom have promised papers for the June meeting, so that the officers can assure the profession of a successful and highly interesting meeting.

Some who were uncertain as to whether or not they could find the time to write are now urged to definitely decide, and it is hoped that some who felt it impossible to do anything, will change their minds, and make an extra effort for this meeting. The few who have not replied to the Secretary's personal letter are earnestly requested to do so at once.

Titles of articles should be sent in as soon as the authors have decided upon their subject.

E. FLETCHER INGALS, Secretary,
70 State St., Chicago.

W. H. DALY, President,
Pittsburgh, Pa.

The names and addresses of Section Officers and other officers of the Association are printed on advertising page 25.

Special Attention is called to the following Rules of the Association:

It shall be the duty of every member of the Association who proposes to present a paper or report to any one of the Sections, to forward either the paper, or a *title* indicative of its contents, and its *length*, to the Chairman of the Committee of Arrangements at least one month before the annual meeting at which the paper or report is to be read. It shall also be the duty of the Chairman and Secretary of each Section to communicate the same information to the Chairman of the Committee of Arrangements concerning such papers and reports as may come into their

possession or knowledge for their respective Sections, the same length of time before the annual meeting. And the Committee of Arrangements shall determine the order of reading or presentation of all such papers, and announce the same in the form of a programme for the use of all members attending the annual meeting. Such programme shall also contain the rules specified in the By-laws and Ordinances concerning the consideration and disposal of all papers in the Sections.

No report or other paper shall be entitled to publication in the volume for the year in which it shall be presented to the Association, unless it be placed in the hands of the Committee of Publication on or before the first day of July. It must also be so prepared as to require no material alteration or addition at the hands of its author.

Every paper or address received by this Association, or by a Section, and ordered to be published, and all reports of Committees, and all plates or other means of illustration, shall be considered the exclusive property of the Association, and shall be published and sold for the exclusive benefit of the Association.

ORDINANCES.

Resolved, That the several Sections of this Association be requested, in the future, to refer no papers or reports to the Committee of Publication, except such as can be fairly classed under one of the three following heads, namely: 1. Such as may contain and establish *positively* new facts, modes of practice, or principles of real value. 2. Such as may contain the results of well-devised original experimental researches. 3. Such as present so complete a review of the facts on any particular subject as to enable the writer to deduce therefrom legitimate conclusions of importance.

Resolved, That the several Sections be requested, in the future, to refer all such papers as may be presented to them for examination by this Association, that contain matter of more or less value, and yet cannot be fairly ranked under either of the heads mentioned in the foregoing resolution, back to their authors with the recommendation that they be published in such regular medical periodicals as said authors may select, with the privilege of placing at the head of such papers, "Read to the Section of the American Medical Association on the day of 18 ." (Vide *Transactions*, vol. xvi, p. 40.)

Resolved, That no report or other paper shall be presented to this Association unless it be so prepared that it can be put at once into the hands of the Permanent Secretary, to be transmitted to the Committee of Publication. (Vide *Transactions*, vol xvii, p. 27.)

SOCIETY PROCEEDINGS.

Massachusetts Medical Society,
Suffolk District.

Stated Meeting January 9, 1889.

SECTION FOR CLINICAL MEDICINE, PATHOLOGY
AND HYGIENE

ALBERT N. BLODGETT, M.D., SECRETARY.

DR. HENRY JACKSON read a paper entitled

NOTES ON TWENTY-SEVEN CASES OF DIPHTHERIA, OCCURRING BETWEEN JULY 1, 1888, AND JANUARY 1, 1889.

(See page 482.)

DR. A. L. MASON opened a discussion on diphtheria with a report of 6 fatal cases of that disease in adults which had recently occurred in the new diphtheria ward at the Boston City Hospital. This ward, which was opened in April, 1888, was stated to be admirably adapted to its purpose, and the nursing was, in the experience of the reader, unequalled, because he knew of no other hospital in this vicinity where the nurses are systematically trained to take care of large numbers of diphtheria patients, a duty which they perform with the greatest intelligence and devotion. Under these favorable conditions for treatment, however, the mortality had been large, many patients, both adults and children, dying from septic poisoning, heart failure in convalescence, and tracheal obstructions. Their state at entrance was often very bad, sometimes moribund. Almost all cases admitted would be classed as severe.

Dr. Mason continued as follows: It will be well, then, to consider how fast this disease has grown upon us, from a few isolated cases thirty years ago, until it is now the most fatal endemic disease of a preventable nature which we have to contend with. The success of our board of health with smallpox makes it proper to assume that the mortality from all infectious diseases could be reduced to a minimum if similar methods could be adopted for their suppression. In this connection I will refer to the report of the Glasgow Fever Hospital, where by isolation and disinfection an improvement in the public health has been obtained.

There are obvious reasons why it is difficult to deal with diphtheria in this community, at present at least, in as summary a manner as with smallpox, although diphtheria is much less contagious, therefore more readily controlled; it is also more fatal, and in many cases it is entirely beyond the reach of medical or surgical aid.

During 1888 the number of deaths from diphtheria in Boston was 470, one third of all the cases reported. This is in excess of the whole number of deaths from yellow fever in Florida

during the recent epidemic, in which there were about 350 deaths in less than 4000 cases, 9 per cent.

At the City hospital, with the assistance of Dr. W. A. Morrison, house-physician, I have found that the records of the diphtheria wards show in 1888 the admission of 199 medical patients and 126 surgical; total, 325; 34 cases were transferred from the medical to the surgical department for operation on account of tracheal obstruction. It will be seen, then, that 160 patients, or nearly half the whole number admitted, required surgical treatment. Of the remaining 165, who were treated medically, 47 died, or 28 per cent. Under 15 years of age, there were 145 admissions with 40 deaths, 27 per cent. Between 15 and 30 years, 6 deaths out of 49 cases, 12 per cent. There were but five patients over 30 years of age, viz., one of 30, one of 31, two of 34, and one of 40 years. One died from tracheal obstruction which was not relieved by tracheotomy.

Direct contagion was reported in about one-fifth of the admissions, but the history in this respect is often deficient. Many of the worst cases come from among the Germans, Poles, Italians, and other foreigners. Two cases came from the same family in six instances; 3 cases, three times; 4 cases, three times; 5 cases, once. Thirty-eight cases from thirteen families.

Among the inmates of the hospital who took the disease were, one of the house-physicians, as previously mentioned, who died after a brief illness; three nurses employed in the diphtheria wards; one nurse in a distant ward; and one laundry maid; all of whom recovered.

In 1880, when the facilities for isolation were imperfect, there were but 71 admissions to the medical department, of whom 7 were hospital employes; 22 per cent. of cases died. In 1887 the rate of mortality, exclusive of surgical cases, was 29 per cent.

It is probable that a large proportion of the gravest cases occurring in the city come to the hospital, especially for tracheotomy. This necessarily makes a high death-rate; 47 per cent. out of a total of all cases admitted in 1887, 184 in number.

DR. G. H. LYMAN said the number of cases of diphtheria has certainly been very startling at the City Hospital, and they presented some features unlike those I have observed in former years. Since October 1st I think there have been under my service 30 cases; 8 of these were transferred for operation, leaving 22 cases, of whom 4 died. There has been another feature in connection with these cases that, I think, has been very striking, and that is the very weak pulse and the low condition of the patient in almost all the cases that I have noticed, certainly in a very large number. Out of these 22 cases there were 4 of distinct heart failure. One of them recovered; the other three died, and

died apparently from a paralysis of the heart; it was not thrombosis; they died easily, quite suddenly; there was no considerable effort required for breathing, no sudden excitement towards the last, which, I suppose, we should look for in cases of thrombosis. With the exception of these cardiac failures there have been none of the cases followed by any symptoms of paralysis elsewhere. In cases of typhoid fever we have had quite a number of patients recover apparently entirely from the typhoid, but we found several of them suffering from neuritis. I have half a dozen cases of neuritis following typhoid fever, but none following diphtheria.

The great prevalence of the disease, it seems to me, is a thing to which prompt attention should be given. I cannot think, in view of the statistics of the Glasgow Hospital Report, that it is a necessary disease. It seems to me something could be done to check it. We can check smallpox; Glasgow people seem to be able to check diphtheria. I see no reason why we cannot do it here as well. The Boston City Hospital has accommodation for twenty-five to thirty diphtheria patients. For a portion of the time the ward has been fairly full, I don't think so full that any cases have been obliged to be placed elsewhere.

The cases Dr. Jackson speaks of, of mild diphtheria or, granting a doubtful diagnosis, follicular tonsillitis, have been quite numerous. We have had a good many cases in which, for twenty-four hours, we did not attempt to make a positive diagnosis. There seems to have been a more constant accompaniment of tonsillar inflammation, distinct from diphtheritic disease, than I have ever noticed before. A good many have turned out to be tonsillitis, but some of them undoubtedly were diphtheria.

The importance of the thing, it seems to me, must be manifest to this Society, but I do not know how we are going to remedy it except through some action of the Board of Health. I think the subject is important enough for this Society to appoint a committee to consult with the Board of Health to see if there is not something to be done to check the spread of this disease. Dr. Jackson mentioned one point that was confirmatory of the general views on the subject; that the disease was decidedly infectious, and *not* contagious. I have always supposed that to be the case, but his statistics and those which the chairman has given bear out my opinion very strongly.

I am rather surprised at the great mortality that the statistics which have been presented give. I did not suppose, from my experience on the medical side of the hospital, that it was anything like that. I suppose the cases turned over to the surgical side were transferred too late, or were of such a character that no operation would relieve the patient. This would increase the general

mortality very much. The operation in a large number of surgical cases—cases extending to the larynx and requiring operation—is done in patients already reduced by the disease, and the mortality is very large indeed. Putting those aside I should say the mortality of diphtheria was small.

DR. DURGIN, Chairman of the City Board of Health: The appointment of a committee would please me very much. I have listened to the remarks with a good deal of interest, and I felt very greatly pleased when I understood that there was to be a portion of this evening taken up with the discussion of the prevalence of diphtheria in Boston. The cause of such a large number being treated at the City Hospital has already been given by the reader. The accommodations have been greatly increased in the past year and, in addition to that, the Board of Health have taken measures to send more patients there than ever before, in consequence of the increased accommodations. I have been somewhat surprised at the very large rate of mortality at the hospital, which undoubtedly is accounted for in a large measure by the fact that the *worst cases* come there; not all, but many of the worst cases, and particularly the surgical cases. The mortality for the whole city, however, has not increased this year; that is, the rate of mortality, the average percentage of mortality of the whole number of cases reported. I have brought in a transcript from the records to show the percentage of mortality of the number of cases reported for the last eleven years; that is, during the period over which we have called for reports from the physicians. I find that the percentage of deaths from diphtheria of the total numbers of cases reported for the past year was 33.18 per cent., and for the past five years the percentage has been 29.16 per cent. against 33.56 per cent. for the previous five years; there having been, as you see, quite a reduction in the percentage of deaths in the total number of cases reported in the last five years compared with the previous five years.

In 1878 we called for reports upon diphtheria, and the first year we received 1,370 reports, with 448 deaths, giving a percentage of 32.7 per cent. for the deaths. For the first five years there were 7,363 cases, and in the last five years 6,134. I wanted to say in this connection that the difference between the official treatment of diphtheria as contrasted with small-pox is certainly very great. In small-pox we have older people to deal with; the average age is considerably higher than with diphtheria, there is therefore less trouble in separating children from parents. In small-pox there is very great fear of the contagion; with diphtheria it is not as great. People will expose themselves and allow others to expose themselves to the one when they would avoid the other. A still greater difference between the two diseases is

in the matter of diagnosis. In small-pox it is very easy, and is almost always made at a very early stage. The physician either recognizes the disease himself at once, or calls an expert to make the diagnosis. In diphtheria it is not so. In diphtheria there is, as we know, oftentimes great difficulty in making a positive diagnosis. The child remains under suspicion for several days if not weeks, therefore the report to the Board of Health is delayed, sometimes until the child has died, and allows the consequent exposure more or less of other children to this disease, both to the family and to people who are liable to call at the house. Another difficulty in the way of treating diphtheria is the difference of opinion in the profession in regard to the true character of croup. There is a question in the Society as to whether croup and diphtheria are one and the same disease, and so long as that difference of opinion exists, so long we shall have a large number of cases of a contagious disease, call it what you may, that will spread from one person to another, and cause croup in our community. The cases are numerous where the disease has spread from one person to another in a family, and beyond the family, while the physician has persisted in calling it croup, and therefore not contagious. Another difficulty which stands in the way of successful treatment by isolation of diphtheria is the fact that in Boston we have no adequate hospital accommodation, notwithstanding the fact that the city has been somewhat generous in providing greater facilities in the past year; and the accommodations, I trust, have not been used to their utmost capacity yet; still, we are constantly running across families where it is almost impossible to separate the children from the parents, or from each other, and the patient remains at home, and thus we constantly have a very large number of points of infection through the city, which never exist with small-pox, and which we cannot overcome. It becomes absolutely necessary, if we would treat diphtheria as we do small-pox, that the Board of Health shall have some place to quarantine such a family, in order to disinfect the house. Again, with small-pox, we have the great advantage of vaccination, which cannot be overrated. There are, in spite of the best we can do, some insurmountable obstacles in the way of treating diphtheria and reducing its prevalence in our city as we might do with small-pox.

DR. GEORGE B. SHATTUCK: We are very grateful to Dr. Mason for bringing before us such a practical subject in such a practical way; and it is only by discussing such a subject in meeting, as we are doing to-night, that we can make some approaches towards creating precisely that public opinion which Dr. Durgin appeals to as necessary for the support of an executive body like the Board of Health; for it is very certain that a Board of Health is limited in its action, first of all by the

powers which the laws give it, and secondly, beyond that, by the condition of public opinion even where the laws support it in active procedures; and our expectations in regard to what the Board of Health can do must be controlled, even beyond and outside of what the laws allow, by the condition of public opinion, which limits what the Board of Health can practically accomplish. I think there is a great deal in the point Dr. Durgin has made with reference to the difference between diphtheria and small-pox. There is an utterly different feeling in the community with reference to small-pox, and one comes across it in all sorts of ways. I remember in a trial in court with reference to typhoid fever, it was perfectly simple to convince the jury and the judge that you could not have a case of small-pox without a preceding case, but as soon as we attempted to tell them they could not have a case of typhoid fever without a preceding case, that seemed to them very extraordinary, a very singular theory indeed, and they immediately wanted to know, if that was so, where the first case came from. With reference to small-pox that difficulty never came to their minds. The public does not reason about these diseases, and you can't do with reference to diphtheria what you do with reference to small-pox.

There is the question of diagnosis. Among some of our brethren who practice medicine, and especially sectarian medicine, a single individual may have three or four hundred cases of diphtheria in his practice in the course of a year, and of this probably the mortality will be absolutely nothing. I remember such an instance not long ago in Springfield, where a distinguished sectarian practitioner described to a society how he had had several hundred cases of diphtheria in the course of the preceding year without any deaths whatever. One of the society, who had taken pains to look up the returns at the registrar's office, showed him and the society that he was mistaken in regard to this. But, of course, the question of diagnosis is a very difficult one, and cases may be returned as diphtheria which are not diphtheria, and, on the other hand, it is perfectly easy to conceal such a disease as diphtheria, which has not any external manifestations. Whilst acknowledging all that, I still sympathize with the feelings which the chairman has expressed; and I think any one on duty at the City Hospital, where we have certainly an opportunity to see as much genuine and serious diphtheria as any other practitioners in this community, if not more, could not help wishing that something could be done. In some cases you cannot force patients to be isolated. I remember one of those unfortunate instances in which almost the whole family—the mother, a child at the breast, and two or three young children—were all brought to the hospital with diphtheria, and one of the children, I think, died; the father came and took the rest

of the family away and took them home against every remonstrance. It does seem as though such a thing as that ought not to be allowed to occur. The father took them back to the same house in which diphtheria had occurred a certain length of time before they had inhabited it, and he took them back there because, he said, he couldn't go anywhere else. He made an effort to get other lodgings, and it was known his family had had diphtheria, and he was driven back to the same lodgings. Such things are constantly presenting themselves to our attention and necessarily make us desire, if possible, that something might be done.

With reference to the mortality at the City Hospital, I don't think it is a large mortality, as mortality from diphtheria is recognized. I think that the statistics of the text-books and of other hospitals will show that the mortality is expected to range rather above 30 per cent. than below it. Many of the cases at the City Hospital are not only the worst cases, but are also, many of them, in the worst possible condition; and I think that it is rather surprising that under these circumstances the mortality should be as small as it is. Without going into the question of treatment I should like to say that, for many years, I have felt that the fact that the mortality has been kept at the point where it is has been largely owing to the extremely skilful and faithful nursing which these patients receive at the City Hospital. I don't believe that that class of diphtheria cases would stand anything like as good a chance anywhere else under other circumstances, and for such cases as these, whilst it is important to have a sensible and experienced physician, I cannot help feeling that it is of fully equal importance to have an intelligent, and faithful, and devoted nurse, who is always on hand to carry out the minutest directions in the most prompt, and regular, and efficient fashion.

DR. G. H. M. ROWE, Superintendent of Boston City Hospital: This is a subject in which I am much interested, as it involves so much experience in regard to the care of the patients with diphtheria at the City Hospital. The Board of Health for several years have appealed to us for greater facilities for the care of patients with contagious diseases. The same thing has been done in the City Hospital Report, in the Trustees' Report, and in the Superintendent's Report, for at least seven years previous to the time when we received our appropriation. Formerly these patients were taken care of in the mixed wards called K and L. The mortality was thought then to be large. The number of nurses who contracted diphtheria was very much larger then than it has been since the new wards were erected. It was only by publishing openly in the City Council the fact that patients had come in there with one disease and contracted another—nine cases in one winter, of whom

four died—that the appropriation was gained. I think it is an open question whether diphtheria wards should be attached to a city hospital; but it was Hobson's choice at that time. The Glasgow Hospital, which has been alluded to by Dr. Mason, is, as far as my knowledge goes, the finest hospital in the world, and the regulations for the separation and isolation of contagious diseases are the best I know of—rules we are not able to enforce at the City Hospital. Our new wards, of course, were experimental in a large measure, but experiments have proved that they are eminently successful in heating and ventilation. There is one fault that could be remedied, and that is that the fresh air supply is not equal to the exit. The system of ventilation is such that fetid odors are carried off rapidly. The accommodations have never been filled to their utmost capacity. We have accommodations for forty-two patients with diphtheria. At no time have there been more than twenty-seven, and it is rare that there are above twenty-two. In previous years the Board of Health has been clamoring for a place to carry these patients. The city government through its Council has supplied such a place, and yet it appears from statistics which are well known to the gentlemen connected with the hospital, that the mortality this year has been something that is, I may say, alarming. It is so much so, and recognized at the hospital to such a degree, that the nurses, although very anxious to see the result of the experiment, become depressed after they get into these wards, and are glad to be relieved and sent elsewhere. They work with the utmost faithfulness, and yet, patients who seem to be doing well often die suddenly from septic symptoms or heart failure. That has a very depressing influence upon the nurses. During the last week in November Dr. Prescott made some statistics. They are not made with reference to publication. They are very nearly the same as those by Dr. Mason. The total number of patients with diphtheria admitted this year was 337. Dr. Mason has given the statistics of the patients admitted on the medical side. I have those who were admitted on the surgical side up to about the 5th or 6th of December. To that date the total cases admitted on the surgical side was 139. Out of that number the deaths were as follows: Tracheotomy was done in 35; of that number 5 recovered and 30 died. Intubations, 71; 54 died and 17 recovered. By another classification, of those cases on whom intubation was first done and subsequently tracheotomy, comprising 16 cases, all died. Out of 17 cases on whom no operation was done, for various reasons, mostly because they were septic and operation deemed useless, 4 recovered and 13 died. That makes a total of 87 deaths. The total deaths were 53 per cent. at that time. The total admissions to the City Hospital in five years have been 960; in four out of five years 333 cases have died.

When the new wards were opened I sent a communication to the trustees recommending certain rules in regard to the isolation of the cases and to the limitation of visitors. It was decided that the practice of admitting friends should go on in a tentative way, and the attempt be made to limit them as far as possible. Practice has shown that what Dr. Durgin says holds true; it is almost impossible to shut out the parents from their children; and if any attempt of that sort is made they immediately take their child away. Our invariable rule is that patients with tracheotomies and intubations are considered as *dangerously* ill. The parents are admitted at all times before 8 o'clock in the evening. We are practically able to exclude all friends except the parents, but beyond that it is very difficult to go in wards attached to the hospital; it is only possible when we have them isolated and separated. The only way to bring this about has been intimated by Drs. Lyman, Shattuck, and others, and that is the creation of public opinion. If the Board of Health cannot do it by its rules and regulations and by expression of opinion through their published reports, and in various other ways; if the City Hospital through its annual report and that of the Superintendent and Trustees are not able to accomplish it, the only way out of it would seem to be that the profession, through its societies, in some formal way should try to educate the people to a better state of public opinion.

A conference with the board of health has been suggested. Until public opinion is created so that it shall influence the uneducated classes, and until some such legal restrictions are made for diphtheria as for smallpox, it seems to me impossible to stop it; when that period is reached it seems to me that a great deal will be accomplished in reducing the mortality, and also in reducing the amount of disease. At the present time there are 18 or 19 cases of diphtheria at the City Hospital. The ward for scarlet fever has been closed, with the exception of 2 cases for nearly three months.

DR. C. F. WITTINGTON: My experience of diphtheria, so far as hospital work is concerned, is limited to the out-patient department of the City Hospital; and I am sorry to say that patients with diphtheria come there, and it is not an infrequent occurrence to find, in looking over the patients in the morning, that a patient with diphtheria has been sitting in immediate contact with other patients in the waiting-room. That, I suppose, is not peculiar to the City hospital out-patient department. The same necessarily must happen more or less in all outside clinics. It is to be hoped that when the new building is completed at the City Hospital some opportunities will be found to question patients at least sufficiently to indicate the possible existence, not only of diphtheria, but of other eruptive diseases, so that these

patients can be removed from contact with the others.

A question which has been of a good deal of interest to me of late has been with reference to the comparative frequency of diphtheria in the various wards of the city. I would like to know if the records at the board of health's office show the distribution as to the wards of the city, because, it seems to me, that it is a matter of considerable importance. It is generally assumed that a great deal of the diphtheria comes from the North End districts, and other more crowded portions of the city. In Roxbury there is considerable prevalence of diphtheria for the last year. One of the cases reported—Case 3—I saw before she entered the hospital. Her surroundings were certainly not such as to give any clue to the origin of the disease in her case. In one house in that district, apparently in perfect sanitary condition, a well-built, large house, in 1876 there was a case of diphtheria in a woman of 60 or upwards, who died. The family then moved away. Two years later a young woman was confined in the house and died of puerperal fever. Her servant went home with a sore throat, which was serious, and whether she recovered from it I do not know. A sister of the lady sick with puerperal fever went home and developed typhoid fever; she was seriously ill. Another family took the house for a year or two, and in 1880 another case of diphtheria occurred in the same house in a child.

Last summer a lecture was published in the *Boston Medical Journal* in regard to the relative frequency of diphtheria in urban and suburban communities. The conclusion was drawn from some fifty different outbreaks of diphtheria, mostly in suburban communities, that in a pretty large number of cases of diphtheria it was impossible to trace the first case of the epidemic from a previous case. In only four out of fifty could the writer trace the first case from a previous case of diphtheria, and he was inclined to believe that a certain number of cases of diphtheria may develop from general insanitary conditions, possibly irrespective of a specific contagion from a previous case. That evidence was tolerably strong in his cases. He cites a number of parishes of over 1000 inhabitants which had a small number of cases of diphtheria in this period of years, while in another series of smaller parishes the frequency of outbreaks were proportionately large. The figures he gives seem to me not to be borne out altogether by the figures in this country, so far as I have been able to ascertain. The last monthly report of the New York State Board of Health, for instance, gives the frequency of the deaths from diphtheria for the month of November, 1888, in the different districts of the State, and of course the mortality by direct conveyance of disease from one to another would naturally be expected to be greater in the cities, but in spite of the fact that

treatment is more active there than in the country districts, the preponderance was greater in cities like Brooklyn, and Albany, and Troy, than in the back-country districts; whereas the report of Dr. Barnes just referred to gives a much larger number of occurrences in the remote districts than in the larger cities. I should like particularly to know whether the occurrence of diphtheria is very much greater in the wards in this city which approximate more nearly the country conditions than in the more crowded wards, or the reverse.

DR. DURGIN: I cannot reply with exactness; but in the past year the distribution has been scattered over the entire city much more than in any previous years. As a matter of guess-work, I believe that the percentage of cases of diphtheria in the population of the out-lying districts is rather greater than that in the more densely populated parts of the city. I think that Dr. McCollom could give a better opinion upon that subject than I, because he sees more of the cases. Dr. McCollom and his assistants usually see most of the cases, particularly those in the central part of the city.

I would like to call attention to one or two points in relation to this disease, and one is the repetition of the disease in the same patient. The text-books, I think, say that one attack seems to predispose the patient to subsequent attacks. Although my own personal experience has not been a large one, this statement of the text-books has not been borne out by my observation; and I have fallen in with very few physicians who have found that that was true. We occasionally hear a patient say that she or he has had diphtheria several times before. Of course that is partial evidence. I know that some physicians have seen a second and perhaps a third attack in the same patient. Of course, if this is largely true, it gives us a much less advantage in taking care of diphtheria than in taking care of most of the other contagious diseases. I should be glad to hear expressions of others who have had experience with diphtheria, on that point.

The matter of removing a patient with diphtheria from the City Hospital is a serious one; legally, I think, neither the trustees nor the board of health would have the right to retain such a patient contrary to his desire.

DR. ROWE: Of course we adapt our policy to the class of people we have to deal with. In a large number of cases we have dissuaded them from removing patients with this disease. In all cases where such patients remove them they are discharged as going on their own request and against advice. We have a printed form for such cases and at the end we state that they remove their child or friend, knowing the disease to be diphtheria and dangerous both to the patient and the public, and they take the entire re-

sponsibility, freeing the hospital and its physicians and the authorities from all responsibility. There is a certain more ignorant class to whom we say, "It is impossible to take your child away." We say it to the Poles and Huns. "You cannot do it without permit from the board of health." If we should make it a test case, there might not be sufficient power with the board of trustees to retain a given case. If patients are taken from the City Hospital, it should be understood that it is not done until after measures are used some, of which are fair and some perhaps not quite truthful, with the more ignorant classes, to retain them.

DR. G. B. SHATTUCK: I should be sorry if any gentleman present got the idea from anything I said, that I supposed, or meant to indicate that there was any power vested in the City Hospital or its board of trustees to prevent such an occurrence. I cited the occurrence to indicate to the society the position of public opinion, and the difficulties in dealing with this question, where such a thing as this was possible and legal, and could be done, and could not be prevented; and it is exactly one of those points which we want to educate public opinion to deal with, and to stimulate our lawmakers to make laws with regard to. With reference to the family I cited, the father there was a very independent, intelligent New Englander. If he had been a Pole or Polish Jew, or German or Austrian, then, as Dr. Rowe says, there would have been some hope of dealing with him, because he is used to a paternal form of government.

It is difficult to make our diagnosis in many of these cases. Then as soon as we have made our diagnosis, it is a pity we have not the power, by law or public opinion, to isolate our patients.

DR. DURGIN: In a case of small-pox we never take a child without its mother or sister with it if possible, and that generally constitutes all the visiting allowed in the hospital. In very few instances the mother has been allowed to come to the hospital after the child has been removed to the hospital, but is always retained until the anxiety is over, and then thoroughly disinfected and carried home. I don't think that the City Hospital trustees or the superintendent can be held to blame at all for the withdrawing of the patient. I don't understand that they have any legal right to retain them.

DR. G. H. LYMAN: I should like to ask the law on that point: if the law gives the board of health the power to isolate a small-pox case why should it not have the right to isolate a case of diphtheria?

DR. DURGIN: It has the same right.

DR. LYMAN: These patients come in by order of the board of health: ought not they to be retained until the board of health gives permission to have them removed?

DR. DURGIN: I don't understand that the board of health has control over a patient after entering the City Hospital. We have the power to start them for the hospital, but no control after they are in it, the hospital not being in charge of the board. The line where our authority begins and ceases in that case is not quite clear. I can only say that when we have left the patient in the charge of the officers of the City Hospital I don't understand that we legally have any further right, can exercise any further control over him. In our own hospital—one established and maintained by ourselves—we would have a perfect right to retain them until all danger from contact with others is passed.

DR. G. H. LYMAN: I should like to ask whether under the law the board of health must isolate all persons in any one special place: cannot the board isolate them in the City Hospital as well as anywhere else? What is the difference? Does the law state that a small-pox hospital shall be for and under the control of the board of health, or that the board of health shall have authority to isolate these cases. Suppose they choose to isolate them in a tent?

DR. DURGIN: In that event we should do precisely as we do in a dwelling house. We place our own officers there. They are our agents and have the right. We cannot make Dr. Rowe an agent of the board of health. We could go there personally if we had the right to retain a patient as in a dwelling-house or in a tent. I give an unprofessional opinion in the matter. It is purely a legal question, which I don't wish to stand in the light of a lawyer in answering.

DR. H. OSGOOD: When a patient leaves the hospital after having been confined a few days, it seems logical to suppose he is in a worse condition than when he enters, and consequently the patient is less protected than when first sent to the hospital, as we will suppose, by the board of health. I would like to ask Dr. Durgin if this society as a body could not present a memorial to any authority, either to the city or the State legislature, which will give the board of health the necessary power, and, if such a memorial would be of use, to what authority should it be presented?

DR. FOWLER suggested that the work of the committee should be directed particularly to the investigating, and to conferring with regard to diphtheria, and not take in the other contagious diseases.

DR. MARION: I have been extremely interested in the papers and the discussion which has been elicited; and I feel quite unequal to saying anything of importance upon the subject, feeling as I do, that the more I see of diphtheria the less positive I am in my opinions as to its nature and everything concerning it; so uncertain am I of late that when I see a case, with reference to

diagnosis I very often say I don't know. What seems to be a case of sore throat may be a case of diphtheria. When asked how long it will last, I tell them frankly I don't know. If the child is not better within a week I think it is very serious. In ward 25, with a population of between nine and ten thousand, during October, November, and December, there were reported to the board of health seventy-four cases, I think, a very large proportion of diphtheria it seems to me, and this has been equally distributed about the ward, not being confined to any particular locality, not confined to streets where they have sewers, to houses where they have water-closets or privies wholly, where they have used well water or water from the mains. No one marked feature has been noticed except that it has been generally distributed through the ward.

With the epidemic or endemic in Brighton, there has been a large number of cases of measles running along with it in the same family.

The matter of heart failure has been referred to. It seems to me I have noticed that phenomenon more in this epidemic than ever before. With reference to heart failure in one family not reported as diphtheria, the child, as the mother told me, was choking. Upon examination, it seemed the child had faucial paralysis with enlarged glands. All the children had had sore throats, this child included. Within a week after I first saw the child I was called again, and found three of the children down with measles. This child was with the rest, came on with the same symptoms, but instead of having a good square eruption it was very pale, the pulse hardly perceptible. The child died that night in the first stage of measles. I returned it as a death of heart failure in the initial stage of measles, heart failure from paralysis due to diphtheria. In two or three other cases of measles I have noticed heart failure.

Dr. Durgin refers to the repeated attacks of diphtheria in the same individual. In this epidemic I had a rather interesting case where a child came down with diphtheria, went through the regular stage of about ten days and recovered, and a day or two following showed the first signs of measles; the measles went through its regular course, and before the child was allowed to leave the room again a membrane developed on the fauces, and I believe it also extended into the larynx, as the child entirely lost the voice and was hoarse several days, but recovered. On the repetition of diphtheria in the child, the mother also came down with diphtheria.

Another subject that Dr. Durgin has alluded to is with reference to croup. I suppose that that is, and always will be, a disputed point. I don't know that all croup is not all diphtheria; there are some cases that certainly don't get reported as diphtheria. A case that has recently happened

in the ward might illustrate what I mean. The children were all sick with measles under the care of a physician practicing sectarian medicine. This child after going through the measles was attacked with croup. The child had the operation of intubation and died within twenty-four hours; was allowed to have a public funeral, was embalmed and had a "wake." Two days after the funeral the remaining two children of the family were sent to the City Hospital by my brother. On the following day I sent the woman to take care of a child during intubation, and subsequent to that there were several cases of diphtheria, but still the first case was claimed to be a case of simon-pure croup. I fancy that oftentimes it goes that way. In connection with diphtheria it was my fortune to see several cases of diphtheria following croup; in most of these instances there was laryngeal complication, even when not coming to a fatal issue. I have an interesting case to allude to in connection with diphtheria in the puerperal state. On the 30th of November, a lady called at my office with a very severe sore throat. Being unable to make a diagnosis I gave her directions to go home and let me know if she saw anything in the throat that looked peculiar. The next night they found a very slight patch. I at once instituted the treatment for diphtheria; and the following day the fauces, soft palate, and both tonsils were covered with the characteristic exudation of diphtheria. She expected to be confined on the 5th of December. The diphtheritic process went on its regular way, and she was confined on the morning of December 5th. Everything went well. She had a very slight elevation of temperature that day; it fell back where it had been before. It did not begin excessively high— 101° or 102° , and in ten days she was convalescent, and within two weeks the fauces, I think, all cleared. The child was taken immediately from the room and in another part of the house. The child was covered with an eruption of sudamina which changed to a milky appearance and disappeared. The mother did well. When the boy was 24 days old I was called to see it, as it could not breathe through its nose. I found a characteristic discharge of thin yellow serum, and felt sure it was going to be a case of nasal diphtheria. The following day a whitish membrane had formed near the anterior opening in both nares, and three or four days after that a patch of diphtheritic membrane had formed in the roof of the baby's mouth, and extended back with just a trace on one tonsil. Further than that it did not extend, and it is still under treatment. The exudation has not disappeared from the roof of the mouth as yet. It is a complication, and when it was first presented I did not know what to think or how to act. It was one of the unusual complications.

DR. MCCOLLOM, in answer to Dr. Withington's question in regard to the prevalence in the different localities of the city, presented a list of the number of cases in Boston for 1888, with the wards and relative area and the number of inhabitants: In ward one, 59 cases. That is East Boston, comprising the hill and a portion adjoining Chelsea. Population, 15,656.

Ward 1	59	15,656	Ward 14	41	22,738
" 2	16	15,700	" 15	49	16,219
" 3	16	12,328	" 16	65	16,435
" 4	28	12,518	" 17	34	14,747
" 5	26	12,827	" 18	27	14,141
(2) " 6	119	17,244	(5) " 19	81	20,577
(6) " 7	97	12,038	(4) " 20	85	27,983
" 8	30	11,286	" 21	40	15,620
" 9	11	11,289	" 22	49	15,834
" 10	11	9,745	" 23	38	17,424
" 11	32	17,865	(3) " 24	110	21,500
" 12	34	13,845	(1) " 25	141	8,523
" 13	35	22,547			
		1,411 cases.			399,597-415,000.

In Dr. Marion's ward (25) 141 cases. Population 8,523. This is a rather remarkable circumstance, because we would naturally suppose that to be the healthiest portion of Boston. A very great number of the houses are isolated, more so in ward 25 than in any other portion of the city, and yet with a population of 8,524 they have had 141 cases. In all there have been reported 1,411 cases throughout the whole city during the year, and the relative frequency is, 1st ward, 25; 2d ward, 6; 3d ward, 24; 4th ward, 20; 5th ward, 19. There is very little to be learned from the other figures, because they are so nearly alike.

A good deal has been said about isolating these cases. Of course it is of importance to isolate them, but how can it be done? We have an entirely different state of affairs in diphtheria from that which exists in smallpox. In the first place we must educate the people up to the idea that diphtheria is *contagious*, and no one more fully realizes the importance or necessity of that than I do. I hear the remarks every day that diphtheria is not contagious. "If the child had smallpox or scarlet-fever we would send the child to the hospital." In some cases where the parents consent to have the child go to the hospital, the family physician comes in and says: "Oh no, you had better not send her to the hospital. The child will be better in a day or two." He can't go against the family physician. No health officers, no one, can remove a patient from any house to a hospital unless the attending physician says that the patient can be removed without injury. We cannot state that there is absolutely and positively no danger. I think very few gentlemen here would care to take a posse of police officers and remove the child from its mother to the hospital, or force the mother to go. It has been done frequently in smallpox, but the community would not sustain the board of health in so doing in cases of diphtheria. It can be done by educating the people up to that point; and through the influence of the members of this Society we can accomplish a good deal.

Take the cases in Brighton. Dr. Marion has sent many cases to the hospitals and done much good. Suppose some one else had been there who did not believe diphtheria was contagious, we might have had ten times as many cases in Brighton as there have been.

Another thing, a good many of these cases are not reported until after the patient's death. It is a common thing for a patient to die, and the first report we get of the case is the death certificate. The patient may have had a physician and the physician told them the child had "sore throat," which is not reported.

It is desirable to have some place where we can send the children who are well, so that they may be watched, and the moment they come down with the disease be sent to the hospital.

As to the question of diagnosis: it is difficult in the first twenty-four hours to say absolutely, "It is diphtheria." We can advise cases to go to the hospital, but when making a forcible removal we must be *sure*. Mild cases are very apt to give rise to trouble, and the same thing is true of all contagious diseases, that the mild cases are very much more dangerous to the public health than the severe cases, because they go round everywhere and spread the disease almost indefinitely. These are some of the difficulties with which we have to contend, and for that reason I have spoken at length about them, because it is important that we take hold of the matter understandingly and see if there is not some way we can stamp out the epidemic to a certain extent.

I have seen quite a number of cases where people have had undoubted attacks of diphtheria a second and even a third time. I have in mind a case where an epidemic went through a whole family; three died and two lived, and since then there have been two attacks of unmistakable diphtheria. So far as hearsay evidence is concerned, we are constantly running across such cases. If a patient can have diphtheria three or four times we must be on our guard more than if they had the disease once in a lifetime.

DR. H. E. MARION presented the specimen of a cast of trachea which he took from a child in 1871, thinking it a case of croup.

DR. FARLOW: As an additional means of preventing the spread of diphtheria it seems to me there is something we can do toward the well children of the family. Diphtheria is a disease much more common in children than in adults. Children are subject to nasal catarrh, etc., consequently they are much more liable to the absorption of germs; so that if there is a contagious disease in the family, I think it is incumbent on the family physician to institute preventive measures, to see if there is any catarrh about the gums, or tonsils in particular, and if so, some alkaline douche should be used. Where there is a suspicion of diphtheria I think the children

should be rigorously inspected. I don't think a physician does his duty who comes into a house, gives a doubtful diagnosis, and says: "Wait two or three days," without instituting some preventive means with regard to the other children; and it seems to me that the prevention is much more important than the cure, although of course, the cure is the thing the family look for. If we can prevent the disease by keeping the throat in a healthy condition we are doing very much more than most physicians are doing now. It is what we should endeavor to accomplish.

DR. G. B. SHATTUCK: Dr. McCollom's remarks with reference to the doubtful cases represent another difficulty—that you can't send these cases to the diphtheria ward of the hospital any more than doubtful cases of small-pox to the small-pox hospital. In cases of sore throat the question comes up, "Is this patient to remain here or be transferred to the diphtheria ward?" Of course, if you send a case of tonsilitis, mild sore throat, to the hospital, and the patient develops diphtheria, it may indicate that your diagnosis is correct, or it may expose you to a suit.

DR. A. N. BLODGETT: In relation to the question of the recurrence of diphtheria I have had one or two cases sufficiently marked to convince me that recurrence of that disease is more frequent than generally supposed. I treated a case of diphtheria, in a young man 20 years of age, in which there was a moderate exudation in the throat of unmistakable character, followed by paresis of almost all the voluntary muscles, so that the limbs were powerless, speech was seriously interfered with, the patient could not move himself in bed, and was absolutely helpless for a period of two or three weeks. From this he gradually recovered, requiring no less than nine months for restoration of strength and vigor. About eighteen months afterward, he was prostrated by another distinct and unmistakable attack of diphtheria: the pharyngeal exudation was distinct and unmistakable, but there was no affection of the nervous system of the kind which occurred from the first case. The two attacks were treated by careful isolation, disinfection, the use of bichloride of mercury, and tincture of the chloride of iron, together with strychnine and other tonics. The patient recovered:

DR. A. L. MASON, in closing the discussion, said: In making these informal remarks about diphtheria I did not wish to convey the impression that the mortality rate seemed to me excessive in the City Hospital. It seems to me the wards are doing their work very well, and I should think would tend to diminish the amount of grave diphtheria that exists in the city. The object of a resolution of this kind is to aid the Board of Health in all its efforts. I am sure all of us are obliged to Dr. Durgin, Dr. McCullom and Dr. Marion for coming this evening and giving us so

much valuable information with regard to the course of this epidemic.

Of course the mortality rate at the City Hospital is made much larger from the number of moribund cases which enter; but the rate of mortality cannot be regarded as excessively high, I think, as compared with statistics from other countries.

DR. LYMAN then presented the following resolution, which was read by the Secretary:

Resolved: That a committee of three be appointed by the Chair to confer with the Board of Health as to the desirability of further measures to limit the spread of diphtheria in Boston. The resolution was adopted.

The Chair appointed Drs. G. H. Lyman, G. B. Shattuck, C. F. Folsom, as that committee.

FOREIGN CORRESPONDENCE.

LETTER FROM PARIS.

(FROM OUR OWN CORRESPONDENT.)

THE PARIS SCHOOL OF MEDICINE. II.

There is only one university in France, one degree, that of Doctor of Medicine, which is conferred by various faculties already named. There is one system of hospitals, all alike open to the student for his one fee. The degrees of Doctor of Surgery and Doctor of Medical Science, may be considered practically obsolete, as one thinks of taking them. Medical teaching in Paris may be divided under the heads of the theoretical teaching given at the Schools of Medicine, and of the hospital teaching which comprehends clinical courses associated with clinical experience. The immense majority of French and foreign students in Paris follow both the official courses of the Faculty and the gratuitous courses given by the physicians or surgeons of the hospitals and unattached teachers. In his third year every student is obliged to attend the hospital regularly, as "stugiaire," or "externe," or "interne." The stugiaires are students following their curriculum, and are divided among the different series of services, medicine, surgery, and midwifery, according to their choice, and must follow the visits of the medical officers during two years, with power to pass from one hospital to the other, but under the obligation to furnish certificates of attendance at the hospitals during 300 days in each year. Students who desire to undertake hospital studies apart from the obligatory curriculum, can attend any of the hospitals under the title of "bénévoles," that is to say, they are not called upon to pay any fee, and they can attend at their pleasure. This privilege is enormously valuable to foreign students. Foreigners are admitted to competition for the "internat" and the "externat." The office of externe or interne can only be obtained

by competitive examinations, and that of interne lasts for four years, and is the stepping-stone to further higher nominations, such as Chefs de Service, and hospital physicians or surgeons. The medical clinics of the Faculty are four in number. For clinical medicine we have Professors Germain Sée at the Hôtel Dieu, Jaccoud at the Pitié, Potain at the Charité, and Peter at the Necker Hospital. For clinical surgery, we have Professors Richet at the Hôtel Dieu, Verneuil at the Pitié, Trélat at the Charité, and Le Fort at the Necker. Besides these official clinics there are a certain number of physicians and surgeons in the hospitals whose voluntary courses are followed. Among these may be mentioned those of Drs. Tillaux at the Hôtel Dieu, Péan at Saint Louis, Labbé at Beaujon, in surgery; and in therapeutics, those of Drs. Dujardin-Beaumetz at Cochin, Huchard at Bichat, and Jules Simon at the Hôpital des Enfants Malades. Foreign students and practitioners who come to Paris to supplement or complete their studies, the whole of the resources of the Faculty of Paris and that of the hospitals are open to them, and those who wish to give themselves up to some specialty have ample opportunities for doing so. Those who wish to study the diseases of the skin will find at the Hôpital Saint Louis unrivalled material. The official course is delivered by Dr. Tourmer, the celebrated syphilographer. For nervous diseases we have Professor Charcot at Salpêtrière, for mental disease, the official course of Professor Ball and the clinique of Dr. Magnan at the Saint Anne Asylum. For diseases of the eyes there is the official clinique of Professor Panas at the Hôtel Dieu. There are a great number of clinics carried on by unattached medical men, who do not form part of the medical corps of the hospitals which the students can follow without being required to pay any fee. These are conducted by Drs. Landolt, Galezowski, and de Wecker, for ophthalmological study, which is also treated of at the hospitals of the Quinze-Vingts. In the study of pathological anatomy may be noted the necropsies of the clinical service of Professor Germain Sée, which are performed at the Hôtel Dieu by Professor Cornil. The teaching of legal medicine, from a theoretical point of view, is carried on at the Faculty, while the practical part of the same branch is carried on at the morgue, both under the direction of Dr. Brouardel, Professor of Forensic Medicine, and Dean of the Faculty. Venereal diseases are especially studied at the Hôpital du Mide for men, and at Lourcine for women. For diseases of the throat there are special consultations held at the Lariboisière by Dr. Gougenheim. For diseases of the ear there are the institutions for the deaf and dumb, at the consultations of which all foreign students are admitted. For accouchments the Clinique of the Faculty, and the maternités of the hospitals, di-

rected by Professor Tarnier at the former, Drs. Budin and Pinard at the Lariboisière and the Charité, respectively. One of the most important special clinics is that conducted by Professor Guyon, at the Necker Hospital, for diseases of the urinary organs. All foreign practitioners or students can attend without payment all the clinics and all the visits of the Professors, and obtain all the information that they desire. They can also by moderate payments obtain private courses of lessons, either from the Internes or from the Chefs de Clinique, at their evening visits at the hospitals. The extensive and important laboratories of MM. Ranvier, Brown-Séquard, Marey, Dastre, etc., at the College of France, are also open to all native and foreign students. Candidates for the office of physician, surgeon, or obstetric officer at the hospitals, are admitted to "concours" on producing evidence of being natives of France, or naturalized, and of having had the degree of Doctor of Medicine for two years, at least. They have to undergo a written and oral examination on the various branches of medicine and surgery. The post of Assistant Professor, or Agrégi, is also filled up after competitive examination.

Dr. Legouest, the well-known military surgeon, died on the 5th inst., at his residence in Paris, in the 69th year of his age. He was Inspector-General of hospitals, and former President of the Council of Health of the Army. He was also Professor of clinical surgery at Val-de-Grâce, and was raised to the dignity of Commander of the Legion of Honor in recognition of his valuable services. He was a member of the Academy of the Medicine since 1867, in the Section of Surgical Pathology. He was President of the Academy in 1881. He was the author of several important works, of which the following may be selected from among them. Besides his thesis for the doctorate in 1845, he published a memoir entitled: *Kystes symbiaux du poignet*, in 1857; *La Chirurgie Militaire Contemporaine*, in 1859; *Une Conférence sur le service de Santé*, in campagne 1868; *Le Service de Santé des Armées Américaines pendant la guerre des Etats Unis de 1861 à 1866*; *Etude sur la salubrité des hôpitaux militaires de Paris*, in 1864; *Traité de Chirurgie d'Armée*, in 1872.

DOMESTIC CORRESPONDENCE.

LETTER FROM CINCINNATI.

(FROM OUR OWN CORRESPONDENT.)

Commencement Exercises at the Medical and Dental Colleges—Cincinnati Academy of Medicine.

The Cincinnati College of Pharmacy held its seventeenth annual Commencement at Musik Verein Hall on the evening of March 14. After the exercises the usual banquet was given. There

were eighteen graduates from the College of Pharmacy this year.

The Commencement exercises of the Cincinnati College of Medicine and Surgery were held in the Scottish Rite Cathedral February 26, where they graduated thirty-two Doctors of Medicine. This is the largest class to leave this institution for some years. Dr. R. C. Stockton Reed made the address of the Dean, and the valedictory address was given by Dr. C. A. L. Reed.

The Commencement of the Ohio College of Dental Surgery was largely attended at College Hall on the evening of March 4. Sixty-five Doctors of Dental Surgery were graduated. The address was made and degrees conferred by Dr. C. R. Taft, as Dr. George W. Keeley, President of the Board of Trustees, had died within the last year. The address to the students was delivered by Mr. E. D. Warfield, the oration by H. M. Paxton. Prof. H. A. Smith, Dean of the Faculty, awarded the prizes, and the exercises were followed by a banquet at the Burnet House for the graduates, faculty and alumni.

The Miami Medical College, at its Commencement at the Odeon the evening of the 6th of March, graduated a class of twenty-two. The remarks by the Dean, Dr. Wm. H. Taylor, were followed by an address from Hon. W. H. McGuffey, President of the Board of Trustees. The valedictory address was delivered by Dr. Byron Stanton, Professor of Gynecology. Dr. Stanton discussed the care of the public health, which field is in his line as Health Officer of the city. The Faculty Prize, \$100 in gold, was awarded Dr. H. E. McVey, of Mt. Blanchard, O. The largest and most enthusiastic meeting of the alumni for some time was held at the Burnet House, where a very enjoyable banquet was given. The Association elected as President, Dr. L. M. Buchwalter; Secretary, Dr. J. C. Oliver. The retiring President, Dr. W. C. Chapman, of Toledo, made a very interesting valedictory address. Dr. Dan. Millikin, of Hamilton, was an excellent toastmaster, and the responses to the various toasts were made in the happiest vein. Two members of the Association were expelled for advertising.

At the seventieth annual Commencement of the Medical College of Ohio eighty-six Doctors of Medicine were graduated. This was held in the Odeon March 7. Dr. W. W. Seely made some short, pointed remarks as Dean of the Faculty. He was followed by the address of the President of the Board of Trustees, Hon. Wm. H. Dickson, who delivered the diplomas. This speaker paid his respects to the neglect of the duties of the politician by physicians. His interesting address urged more attention to the affairs of the country by doctors and the assumption of an active part therein. The Faculty Prize for the best final examination in all departments was captured by Dr. Erwin O. Strachley, of Cincinnati. Dr. For-

cheimer, Professor of Physiology and Diseases of Children, delivered the valedictory address, advocating his subject, "Specialism in Medicine," with many good arguments.

The alumni of the Medical College of Ohio met at Memorial Hall the afternoon of March 7. An address was made by the President, Dr. S. J. Spees, of Hillsboro, Ohio. "Politics and the Doctor" was the subject of the annual address, delivered by Dr. Miles F. Porter, of Fort Wayne, Ind. The matter of the publication of the early history of the College from 1819 to the present was placed in the hands of a committee.

At a recent meeting of the Academy a report was made by a gentleman on the radical cure of hernia. His paper was very able and was listened to with close attention. At the end he wished to show three male patients on whom he had operated successfully. Two lady members of the Academy were present and the men positively refused to exhibit unless the ladies absented themselves. The President descended from his chair and asked the ladies to be kind enough to retire, which they did. The patients then took their stand on the rostrum and were inspected by all present who wished to do so. At the next meeting one of the ladies, having taken offense at being deprived of her inalienable rights, immediately after the reading of the minutes demanded an explanation of why she had been excluded from a part of the previous meeting. The President tried to satisfy the lady M.D. with an evasive answer which was rendered all the more transparent by the diffidence with which it was given. The lady asked with renewed emphasis why she was requested to withdraw, and still remained unsatisfied when the President told her that the men refused to exhibit themselves unless the ladies were absent.

MC. K.

Commencement Exercises of the Chicago Medical College, Medical Department of the Northwestern University.

Mr. Editor:—While attending the Thirtieth Annual Commencement Exercises of the above-named college, on the 26th of March, 1889, I noted the following items that will be of more or less interest to your readers in all parts of the country. The college was organized on the basis of a strictly graded system of medical education, and requires a fair standard of preliminary education for admission, three full years of medical study, including three annual courses of medical college instruction of not less than six months each, with laboratory and hospital clinical attendance two college courses. During the college year just closed the classes in attendance numbered as follows: 1st year class 79; 2d year class 52; 3d year class 51; making a total of 182.

After music, and the opening prayer by Rev.

Joseph Cummings, D.D., L.L.D., President of the University, the Dean of the medical faculty announced the awarding of the following prizes :

The Fowler Prize, being a case of test lenses worth \$100, given by E. S. & W. S. Fowler, of Chicago, to that student of the Chicago Medical College who at the close of this session shows the most proficiency in theoretical and practical optics, was awarded, after careful examination, to Carleton Montville Balfour, of Kansas.

The Fuller Prize, of \$25, for the best graduating thesis on Puerperal Fever was divided. Of the competitors two show such equal merit that the committee concluded to divide the prize and give one-half to Abraham Lincoln Blesh, of Kansas, and one-half to E. J. Boeseke, of California.

A prize, consisting of a case of amputating instruments, offered by Dr. A. J. Coey to the member of the Clinical Class in Mercy Hospital who should write the best thesis on the Differential Diagnosis of Injuries of the Hip-joint, was awarded by the proper committee to E. J. Boeseke, of California.

The Faculty Prize for the best thesis has been awarded to the author of the thesis on the "Etiology, Pathology and Treatment of Thermic Fever," Francis William McNamara, of Illinois. This thesis is not only well written but it also contains the results of some important original investigations. The theses of Pierrepont Isham Prentice, George William Harkins, Daniel Webster Eiss, and James Perry Houston, are also worthy of special commendation.

Ingals Prize.—Two years since, Dr. Ephraim Ingals, well known as one of the older and most highly esteemed physicians of this city, wishing to encourage a higher standard of general education and mental discipline for students of medicine, instituted a prize of \$100, to be awarded to the member of the graduating class in this College who should attain the highest average standing in literature, science and medicine; the same to be determined by a committee of the medical faculty. One year since, in furtherance of the same object, Dr. Geo. Wheeler Jones, of Danville, Ill., offered a prize of \$50, to be awarded to the member of the graduating class of 1889 who attained the second position in the contest for the Ingals prize. The committee having charge of the examination for these prizes required the same to be conducted in writing, and to include, under the head of *Literature*, English composition, rhetoric, logic, history, and English literature; under *Science*, algebra, physics, botany, natural history, and the topography and geology of the United States; and under *Medicine*, all the branches of medicine and surgery included in the curriculum of the medical college. All who entered the contest were graduates of literary colleges or universities, some in the East and some in the West. After careful

comparison of the results of the examination the committee unanimously awarded the Ingals Prize of \$100 to James Perry Houston, of Ohio, and the Jones Prize of \$50 to Leonard Lawshe Skelton, of Illinois.

In formally presenting the graduating class to the President of the University for the degree of Doctor of Medicine, the Dean of the medical faculty gave the following interesting items of their collegiate history :

The class entered the College as first year students in 1886, numbering 53, and were examined at the close of that college year in all the branches of the first year course. Only 37 of the number returned for the second year course, 16 having been lost; but 10 new students coming from other colleges were admitted by examination for advanced standing, making the number for the second year 47. Of this number 43 returned for the third year course, 4 only having been lost. To these 8 who had spent two years in other medical colleges were admitted by examination for advanced standing, making the whole number in the third year class 51. Of these 46 were presented by the President of the University, as having complied with all the requirements of the College and passed satisfactorily all examinations, for the degree of Doctor of Medicine. Of this number 18, or a fraction less than 40 per cent., were regular graduates of literary and scientific colleges, and the remaining 28 had pursued academic and collegiate studies from one to five years before commencing the study of medicine.

The whole number of matriculates in the College this year being 182, it will be seen that the ratio of graduates to matriculates is only a fraction over 25 per cent. Such is the result of a rigidly graded and faithfully executed three years course of medical studies.

S. M.

MISCELLANY.

STATE MEDICAL SOCIETY OF TENNESSEE.—This Society will meet in annual session at Nashville, April 30, and continue in session three days. Tickets to Nashville can be bought at that time in all the Southern States at one fare for the round trip, good for ten or more days. G. C. Savage, M.D., Chairman Com. of Arrangements.

SEVENTH DECENNIAL CONVENTION FOR REVISING THE PHARMACOPEIA OF THE UNITED STATES OF AMERICA.—Notice is hereby given that, in accordance with and by virtue of the authority vested in me by the Convention of 1880, I hereby call upon the several incorporated Medical Societies, incorporated Medical Colleges, incorporated Colleges of Pharmacy, and incorporated Pharmaceutical Societies throughout the United States of America, the American Medical Association, and the American Pharmaceutical Association, to elect a number of delegates, not exceeding *three*, and upon the Surgeon-General of the Army, Surgeon-General of the Navy, and the Surgeon-General of the Marine-Hospital Service, to appoint, each, not exceeding *three* medical officers to at-

tend a General Convention for the Revision and Publication of the Pharmacopœia of the United States of America, to assemble in the city of Washington, D. C., on the first Wednesday of May, 1890 (May 7th), at twelve o'clock noon.

The several bodies, as well as the Medical Departments of the Army, Navy, and Marine-Hospital Service, are hereby requested to submit the Pharmacopœia to a careful revision and to transmit the result of their labors to the Committee of Revision at least three months before the meeting of the General Convention.

The several medical and pharmaceutical bodies are hereby requested to transmit to me, as the President of the Convention of 1880, the names and residences of their respective delegates, as soon as they shall have been appointed; a list of these delegates shall thereupon be published under my authority, for the information of the medical public, in the newspapers and medical journals in the month of March, 1890.

In the event of the death, resignation or inability of the President of the Convention of 1880 to act, these duties (in accordance with the resolution of that Convention) shall devolve, successively, in the following order of precedence: upon the Vice-Presidents, the Secretary, the Asst. Secretary, and the Chairman of the Committee of Revision and Publication of the Pharmacopœia.

These officers are as follows: First Vice-President, Samuel C. Busey, M.D., of Washington, D. C.; Second Vice-President, P. W. Bedford, Ph.G., of New York; Secretary, Frederick A. Castle, M.D., of New York; Assistant Secretary, C. H. A. Kleinschmidt, M.D., of Washington, D. C.; Chairman of Committee of Revision, Charles Rice, Ph.D., of New York; First Vice-Chairman of the Committee of Revision, Joseph P. Remington, Ph.D., of Philadelphia, Pa.; Second Vice-Chairman of the Committee of Revision, C. Lewis Diehl, Ph.G., of Louisville, Ky.

At the General Convention held in Washington, D. C., on the fifth day of May, 1880, the organizations and bodies enumerated in the Abstract of the Proceedings of the National Convention of 1880, on pp. xv. to xviii of the U. S. Pharmacopœia of 1882—a list of which will be found appended to this call—were recognized as being entitled to representation.

If any body other than those admitted in 1880 shall desire a representation in the Convention of 1890, it is suggested that the proof of incorporation, signed by the Secretary of State, of the State which shall have issued the charter, or by properly qualified public officials of the United States, be presented with the credentials of the delegation.

A blank form of certificate of appointment of delegates will be sent upon application by letter to my address, care of Dr. Edwin H. Brigham, Assistant Librarian of the Boston Medical Library, 19 Boylston Place, Boston, Mass. (Signed)

ROBERT AMORY, Pres't of the Convention of 1880.
Boston, March 9, 1889.

LETTERS RECEIVED.

Dr. John P. Stoddard, Muskegon, Mich.; Dr. Wm. B. Canfield, Baltimore, Md.; Dr. J. H. Fiegenbaum, Alton, Ill.; J. J. Kindred, Louisville, Ky.; Dr. J. T. Cron, Carrollton, Ill.; E. W. Woodruff, Black Lick, O.; Parke, Davis & Co., Detroit, Mich.; Dr. G. C. Savage, Nashville, Tenn.; Dr. A. L. Hummel, Philadelphia; Dr. Willis P. King, Kansas City, Mo.; Dr. John I. Miller, Wellston, Mo.; Dr. Leonard St. John, Chicago; Plimpton Mfg. Co., Hartford, Conn.; I. Haldenstein, New York; New York & Chicago Chemical Co., New York; Thos. Leeming & Co., New York; American Advertising Agency, Cincinnati, O.; Dr. Russell Bayly, New York; Dr. Willard Streetman, Sweetwater, Tex.; Dr. M. W. White, Sioux City, Ia.; Miss Maggie Kennedy, Carterville, Illinois; Eisner & Mendelson Co., New York; A. E. Walesby, O.

Stubville, Louisville, Ky.; J. Walter Thompson, New York; Clark Bell, New York; Dr. E. Fletcher Ingals, Chicago; Dr. R. J. Dunglison, Philadelphia; J. S. Dorsey, Baltimore, Md.; F. T. McFadden, New York; Longmans, Green & Co., New York; Dr. S. B. W. McLeod, New York; Walter Baker & Co., Boston; Boston Gynecological Society; Cincinnati Polyclinic; Dr. Hamline, Marysville, Cal.; A. M. McLaurie, New York; Ward Bros., Jacksonville, Ill.; Dr. J. W. Park, Williamstown, Pa.; Dr. Charles F. Disen, Seattle, W. T.; J. B. Imhoff, Chester, Pa.; Dr. W. H. Keller, Jersey City, N. J.; Dr. Emil Pfeiffer, Wiesbaden; M. Goltman, Montreal, Can.; Thos. S. Blair, Ann Arbor, Mich.; Dr. G. W. Galloway, Findlay, O.; D. Kimball, Chicago; Nugent, Brown & Co., Fargo, Dak.; Provident Chemical Works, St. Louis; Lambert Pharmaceutical Co., St. Louis; Wm. Burnett, Montreal, Can.; Dr. Moreau R. Brown, Chicago; Eisner & Mendelson Co., New York; J. H. Basinger, Louisville, Ky.; L. Victoria Hampton, Portland, Oregon; Union Pacific Railway Co., Omaha, Neb.; Dr. Richard J. Dunglison, Philadelphia; Henry Bernd & Co., St. Louis; Dr. H. B. Ransom, Chicago; New York Pharmaceutical Co., Bedford Springs, Mass.; Dr. L. THE USE OF ELECTRICITY IN THE TREATMENT OF DISEASES OF THE FEMALE PELVIC ORGANS.

*Read before the Medical Society of the District of Columbia,
December 10, 1888.*

BY J. WESLEY BOVEE, M.D.,
OF WASHINGTON, D. C.

Electricity is not unlike all other things in medicine, as regards its invariable tendency to do good even when applied under the most favorable conditions and in the most careful manner. Yet, a great deal of good can be done with it when it is wisely used. It has, I think, been used in medicine about sixty-five or seventy years, and during that period nearly all diseases have been subjected more or less to its influence—usually without any regard to system and frequently without any evidence of reason. This is probably due to the lack of knowledge as to its method of influencing living tissues. During the last few years it has received more attention from scientific men, and its effect upon the human system has been quite thoroughly investigated. The conditions in which it is likely to prove valuable as a means of treatment, have, to a great extent, been classified. For about three years it has been carefully studied in relation with female pelvic troubles, such as fibroid tumors, inflammatory deposits of long-standing, subinvolution and ovarian neuralgia.

The treatment of extra-uterine pregnancy in its first few months has probably become the greatest field for it, inasmuch as many so-called cases have, in this country, been reported cured by it, and the majority of prominent gynecologists of this country prefer its application to the use of the knife during the first five or six months of this condition. No uniform rules are followed in its application to erratic gestation, some preferring the faradic current, but most advocating the galvanic—claiming it is less liable to produce rupture of the gestation sac. But few of these cases have, I think, been positively diagnosed, and I believe in but two or three cases in which electricity has been used for this unfortunate condition, have the products of conception

actually been seen. I saw one of these, and assisted in removing, per vaginam, a five months' fœtus from Douglas' cul-de-sac. The reporter of the case claimed to have diagnosed the condition during the thirteenth week, and began applying the galvanic current. This was continued about three weeks, and the extra-uterine growth continued to increase in size after the use of the galvanic current was discontinued. It is interesting to know that electricity was passed through the pelvic organs two or three times during the month, just after the last menstrual period. I can hardly attribute the death of this fœtus after the end of the fifth month to the use of the galvanic current between the twelfth and the fifteenth week.

Great claims are being presented for the efficacy of the galvanic current in dispersing fibroid tumors of the uterus. Particularly is it advocated in this class of cases by Apostoli, Keith, Newman, Freeman, Engelmann and Cutter. Its value in this direction is, I believe, overrated.

In two cases that I had diagnosed uterine fibroids, the growths disappeared after several applications of the electric current. One of these was, as I thought, a fibroid of about one and one-half inches in diameter, situated in the posterior wall of the uterus. The woman's general health was bad, but rapidly improved while using a mild galvanic current twelve times in four weeks. At the expiration of the time mentioned, the uterus had become perfectly normal. My diagnosis was made the first time I saw her, and three subsequent examinations did not lead me to doubt the correctness of it.

The other case was multiple fibroids of the uterus and very troublesome. In this case I used the faradic current to relieve pelvic symptoms. These tumors also disappeared. I believe, however, the electric current was not the real factor in their removal, inasmuch as such growths frequently disappear without any treatment whatever. The other case, I now believe, to have been incorrectly diagnosed, that no tumor existed, and that something else was the enlargement I felt—possibly a hypertrophic thickening of the posterior wall of the uterus. My reason for thinking I erred in the diagnosis is that I

have treated with galvanism quite a number of patients suffering with uterine fibroids of various sizes, shapes, locations, etc., the treatment in most of them being diligently pursued for some months, and in none of them, except the above mentioned, did I notice any diminution in the size of the growth during the treatment. One of the two cases cited was one of the first subjected to this kind of treatment, and I was then too enthusiastic in the work to pause for impartial reasoning or to think I might be wrong.

At any rate, I cannot see what reason the advocates of "electrolysis of fibroids" have for so terming the electric action they describe. Certainly no breaking up of the chemical constituents of the growths occur, except, perhaps, some simple salt like sodium chloride is decomposed. But the albumenoids and other complex proximate principles are not broken up, consequently electrolysis does not occur.

Even if it does take place at the poles chemical change does not extend any appreciable distance into the growth. In hard fibroids of from nine to twelve inches in diameter, I cannot conceive how any electrolytic action can take place throughout the tumor, without irreparable damage to the delicate adjacent tissues. How can a current so powerful be confined to the growth when the surrounding more delicate tissue has so much greater conductivity.

The galvanic current has been used considerably in the treatment of inflammatory deposits about the uterus, punctures having been made and powerful currents used as in the treatment of fibroids. I believe mild currents, if applied oftener and longer, both in duration of application and period of treatment, will prove more serviceable. This has been the plan of treatment of the cases related in this paper.

The profession, in general, has not shown much ambition in the treatment of acute inflammations with electricity. I have frequently used it in decidedly acute inflammations, and even in the first stage with most excellent effect. I was pleased by a short article on that subject by Dr. E. H. Grandin, of New York, that appeared in an August number of the *Medical Record*, (Vide vol. xxxiv, 204, 1888.) My limited experience is in accord with that of Dr. Grandin. I think the electric current, either the galvanic or the faradic may many times be wisely substituted for the knife in diseases of the ovaries and oviducts. Mr. Lawson Tait, basing his opinion upon a few cases that came to him for operation after having been treated by electricity (no description of this treatment being offered), denounces strongly, the application of electricity for such cases, (Vide *Medical Record*, N. Y., 1888, xxxiv, 553.) I do not believe that had Mr. Tait given electricity a fair trial in his own practice he would have yet reported his second thousand of consecutive ab-

dominal sections. He has become so expert in abdominal surgery that I doubt his allowing this form of treatment to be superceded by any other, without great reluctance.

I have had a few cases in which the action of the continued galvanic as well as the faradic current has been positively intolerable. The history of one of them appears in this paper (case No. 8).

Certainly case No. 7 was far more nervous than this patient, yet the effect was so decidedly opposite to the result in No. 8.

There is a class of cases that cannot tolerate the application of electricity—not even the amount of electro-motive force just sufficient to overcome the resistance of the tissues through which it passes. I am unable to see anything about these patients that could, in any respect account for the intolerance of the current. It is probably an idiosyncrasy that will only be known after attempts to apply the current have been made. The batteries I have used were made by Waite & Bartlett, of New York, and have been faithfully cared for. I have usually applied the galvanic current just strong enough to be not uncomfortable to the patient. Each séance usually lasted from fifteen to thirty minutes, and usually repeated on alternate days, but occasionally, applications were made every day. The treatment was usually supplemented by tamponnement with small woolen pledgets that were left *in situ* until just before the patient was to return for another treatment. The galvanic current was used in every case, and occasionally the faradic current was employed for its tonic effect, and for the relief of pain. It was usually successful in both of these, and its salutary effect upon constipation was occasionally noticed. I append the histories of a few cases, mostly chronic, pelvic inflammations showing the effect of the mild, galvanic current.

Case 1.—Mrs. W., æt. 31 years; widow; has three children, the youngest being 3 years old. Last confinement severe—finally delivered instrumentally. Has been an invalid since that event, cannot walk one block; suffers very much with pain in "bottom of stomach"—constant fear her "insides" will fall out; constipated; has continuous discharge from bowels. Menses regular and profuse; appetite poor; general condition bad. I first saw her when she came to my office in a carriage, July 29, last.

An examination revealed perineum torn almost into bowel, and a glairy discharge from rectum. The uterus was very low, considerably enlarged, and firmly retained in a retroverted position by the dense and thick adhesions from a former cellulitis. The cervix uteri was deeply lacerated bilaterally. I applied the galvanic current for twenty minutes, placing the positive pole against the roof of the vagina and the negative on the abdominal wall just a little above the symphysis

pubis, and applied a few woolen pledgets against the retroverted fundus uteri for gradual pressure. I also gave her the following: *R. Tr. nucis. vomicæ, tr. belladon. āā ʒss. m. et. sig. 15 drops t.i.d. in water.* This treatment was continued quite regularly three times a week, until October 9, when the pelvic deposit having been entirely absorbed, the uterus in good position, and the patient's general condition much improved, I operated for the perineal and cervical tears. The union was complete in both localities, and three weeks later, she resumed her household duties. November 25, I examined this patient, and found the pelvic organs in a perfectly healthy condition. A Simpson sound passed into uterus three inches. She said she had gained thirty pounds in weight since August 1, last, notwithstanding the two operations she underwent in the meantime.

Case 2.—Mrs. H., white, æt. 32 years; came to me September 31, last, and gave the following history: At the age of 20 years she married and had two children, both of which are now living. Her husband died six years later. During one of her confinements the cervix uteri was torn, and she had womb trouble following it. During her widowhood she was operated upon for the laceration, and was married again about two years ago. She felt well until last spring, when she had an abortion produced, and was in bed about three weeks following it. The doctor told her she nearly died from fever. Has not felt well since, is thin, delicate and nervous; suffers with profuse menstrual flow every three weeks, and constant bearing-down pain with headache. After walking a short distance she is obliged to lie down. An examination revealed the uterus retroverted and bound down by a firm pelvic exudate on every side. The sound passed three inches, the cervix tender, considerable catarrhal discharge was seen oozing from its canal. Applied a solution of silver nitrate (20 grains to ʒj) to cervical canal and dry wool tamponade to posterior fornix vaginæ. Two days later she returned, and I began a course of treatment by the galvanic current, as in case 1, extending the séance to thirty minutes and applying the wool as before. October 16, made the seventh application.

I succeeded in replacing the uterus, which has no tenderness nor catarrhal discharge. Patient states she has gained six pounds since her first visit, and feels comparatively good. November 4 to 6, menstruated—no pain and normal quantity. Treatment continued until November 16, when it was discontinued. The uterus was then in normal position, sound passed two and three-fourth inches, and no pelvic adhesions can be found. She feels perfectly well.

Case 3.—Mrs. H., white, æt. 34 years; married. I was called to see her June 28, last, and found her

suffering with a large pelvic abscess to the left of and behind the uterus, reaching up into left inguinal region. She had been married twelve years and had three children. Since the birth of the last child, she has had three abortions. Since her last confinement, six years ago, she has suffered with womb trouble; menstruation occurred in latter April, but she did not think she was pregnant again, as no symptom as in former pregnancies was present, except nervousness. She was taken with severe pelvic pains with hæmorrhage from the uterus on the 17th of June. This began without warning a short time after coming in from a drive behind a fractious horse that afternoon. The pains continued until near morning, when her doctor said she passed something that she now thinks was the result of another abortion. She had fever a few days later and great swelling and pain in lower abdomen. She suffered so much with pain, that her doctor gave her suppositories of morphia and belladonna, but the fever had never gone away. On my first visit I found her in bed, with a feeble pulse, some fever and a hectic flush to cheeks; an eruption all over the body, that she stated had appeared during the past week. I attributed it to the use of belladonna, and it shortly disappeared after I stopped the suppositories. The uterus was found enlarged, immovable, and very tender. It was pushed forward and to the right by a large abscess that was quite prominent in left inguinal region; fluctuation was distinct through Douglas' pouch as well as through abdominal wall. Considerable sanious discharge from uterus was present. The same day I opened the abscess through the abdominal wall and let out about a quart of yellow pus. A grooved director was then pushed through the vaginal roof in the median line, behind the cervix uteri against my right index finger, in the bottom of the abscess cavity. Through the new opening I forced my left index finger. The cavity was then flushed with about a gallon of hot solution of corrosive sublimate, 1 to 1,000. A long rubber drainage tube was passed through the abdominal opening and pulled out through vagina. The solution of mercuric chloride was used for cleansing the wound. Patient rapidly improved, and the abscess was healed by the 10th of August. August 27, she came to my office. Had just had a troublesome and profuse menstrual period and felt weak, complained of little jars received in riding on street car. The uterus was found still immovable, somewhat enlarged, very hard and settled back to a position about normal. The whole pelvic organs seemed to be in a mass as if set in plaster of Paris. I began using a mild galvanic current, the positive pole applied to vaginal roof performing the work. The current was used twenty minutes, and this frequently followed by the negative pole of the faradic current along the spine

for five minutes. She was also given the following prescription :

R. Hydrarg. bichlor. gr. jss.
Tr. ferri chlor. ʒv.
Syr. zingiber. ʒj.
Aque ad ʒiv.
℞. et. sig. Teaspoonful in water after meals.

This treatment was continued until October 26, at which time she was obliged to return to her home in Pennsylvania. The galvanic current had been applied about three times a week. At her last visit she stated she had just passed her menstrual period, and with very little inconvenience. A careful examination was made at this time. Her general condition was much better and she complained very little. The uterus was fairly movable, although no smaller, but the pelvic exudate was lessened in amount and softened.

Case 4.—Mrs. S. M., a widow, 44 years old, first came to me June 15 last. She had had three children, the last of which was born fourteen years ago. This labor was severe; she was delivered by forceps and torn. She had child-bed fever and made a bad getting up. She has suffered ever since with profuse menstruation every three weeks, sometimes oftener, and a sensation of weight in her stomach. Large clots were passed every time she was unwell, and the prostration incident to each attack would hardly be overcome in the interval following it. She has been treated by three or four physicians, all of whom told her her trouble was fibroid tumors of the uterus and treated her with ergot and other remedies. Her last physician, after a course of treatment extending over six months, told her relief would come only with the change of life. Her appetite was poor and the feeling of weight pronounced. I found the perineum torn down to sphincter ani muscle, the vaginal walls flabby, and the uterus symmetrically enlarged to about twice its natural size, a little lower than it should be and fixed. The cervix was bilaterally lacerated almost to the cervico-vaginal junction and the vaginal roof thickened and very dense. I could not find a fibroid tumor, and so informed her. I applied the galvanic current as in the other cases, with the occasional application of the positive pole to the interior of the uterus a few days before the expected flow. Dry woolen pledgets were also placed against roof of vagina, sufficiently large to cause slight upward pressure. I noticed the intra-uterine electrode passed the first time $4\frac{1}{2}$ inches. She improved considerably, the hemorrhages lessened in amount and frequency. Early in August the intra-uterine electrode would pass but $3\frac{1}{2}$ inches. The flow did not appear in September until near the natural time, and in October it was quite four weeks later, lasting but three days and containing no clots. It did not appear at all in November—no premonition of it even appearing.

November 3. The uterus is movable to a considerable degree, and is smaller, its cavity measuring but 3 inches. There is yet some thickening of the vaginal roof.

Case 5.—Miss C., æt. 32 years, white, first came under my care July 12 last, when she came to my office, accompanied by her mother. Her history is as follows:

Began menstruating at 12 years, has never missed a period, nor been free from pain at that time. Has become very severe during the past two years, requiring her to take $\frac{1}{2}$ gr. morphia suppositories, and to remain in bed the day preceding the beginning of the flow, and during the first two days of it. The last period was the worst of her life and she dreads the next—three weeks off.

During the intermenstrual periods she has a dull, heavy pain in lower part of abdomen, most marked on the left side. Her appetite is poor and she is troubled with constipation. Has been treated in Richmond and Philadelphia. She and her mother feared the ovaries would have to be removed, as that had been advised in Richmond, and in Philadelphia they were told nothing else would cure her. She readily consented to an examination, which revealed a small, retroflexed uterus and enlarged and unusually tender ovaries which could be fairly well outlined by the bimanual method of examination, the patient lying in the lithotomy position. They were low but movable. I began to use the galvanic current that day, applying it every day thirty minutes. The current was very comfortable to the patient. After it was stopped I applied a small pledget of wool against the fundus uteri and allowed it to remain there until just before her return the next day. Once I had to give her a mild laxative. This treatment was continued until she came August 4. She preferred no treatment that day, as she felt she was going to be unwell soon. She was suffering from pain through the pelvis. She consented, however, to be treated, and I applied the positive pole of a mild faradic current to the uterine cavity for about ten minutes—the negative pole being placed over hypogastrium. She began menstruating during the following night and had very little pain, but remained in bed for two days. The flow lasted four days.

August 11. Patient returned and treatment resumed. An examination at this time showed the ovaries to be less tender and their position a little higher. I pursued the treatment of this patient diligently, hoping to render oöphorectomy unnecessary.

The next menstrual period was passed with but slight uneasiness and she did not remain in bed. After this period the ovaries could not be felt with the patient lying on her back. I continued the galvanic current for three weeks—applying it on alternate days after the last menstrual epoch. At this time, September 28, she went to her home in

Virginia. At her last visit to me I carefully examined her pelvic organs. The uterus I found in a better position than at first and, I think, a little larger. The whole pelvic viscera had lost its unusual tenderness. She stated she had gained in weight 6 lbs. I have not heard from her since she left the city, but think she would return if she was not feeling well.

Case 6.—K. S., æt. 24, white, single, came to me June 15 last, suffering with almost constant pain in lower abdomen, that gets worse after walking even a short distance. Menses profuse and painful, occurring irregularly, although about every three weeks. She cannot go up and down stairs without considerable pain, and that interferes materially with the proper performance of her duties as housekeeper in a large boarding-house. She confessed having had an abortion performed in June, 1886, after having missed two menstrual periods, and did not get along well afterward, although she did not consult a physician. An examination revealed a dense vaginal roof, holding quite firmly an enlarged, congested and tender uterus; considerable catarrhal discharge was oozing from the eroded cervical canal. A solution of alum in glycerine was applied to the canal and the galvanic current was passed through the inflammatory deposit. A small pledget of dry wool containing some powdered borax was laid against the external os uteri. The discharge from the canal ceased about the middle of July. The galvanic current was applied thirty-six times, the last application being made October 12, when the uterus was movable, reduced in size to about normal, and the cellular tissue about it showed no abnormal deposit. She was feeling very well and had passed the last two menstrual periods four weeks apart, without pain or undue quantity of flow. She was working every day.

Case 7.—Mrs. B., white, æt. 22 years; she is a tall, thin blonde and has been married six months. She came under my care October 4 last. She had generally had a great deal of pain at the menstrual period, but it has been worse since the date of her marriage. The first menstrual epoch after her marriage was two weeks late, and then appeared only after her taking medicine upon the supposition that she was pregnant. She did not desire children and believes she prevented it in this instance. She was confined to bed afterwards with pain so severe that, as she says, she had to take large doses of paregoric to live. She has felt badly ever since, suffering with extreme tenderness in lower abdomen and pain in back. Her last menstrual period ceased one week ago.

At her first visit she appeared weak, pale and nervous. The conjunctivæ were pale, and she walked slowly and carefully with a slight limping on the left side. She complained of frequent and painful micturition, loss of appetite with frequent nausea, constipation and night sweats.

She thought she had malaria, as she was having a chill every day.

October 5 I examined her and found the vagina short and its walls deeply congested and tender. The uterus, retroflexed and retroverted, was quite firmly held in that position by a thick cellutic deposit to the left and behind it. The eroded cervix uteri was covered by a thick muco-purulent discharge. Applied the galvanic current three times a week. October 10, she felt much better. I added faradization of the spinal cord as a tonic.

This treatment continued until October 31, when patient stated she felt real well and had gained 6 lbs. She has no trouble with stomach, bowels or bladder. The uterus is movable but enlarged, very little inflammatory thickening to roof now felt. Uterus easily pushed forward but no discharge from cervical canal; appetite good, no nausea.

The positive pole was applied after this, each time, to the interior of the uterus until the 12th of November. On the 20th she returned to state that she felt perfectly well, and had menstruated four days since her last visit; did not feel uncomfortable during it and is now doing her own housework. She has no limping and has no trouble from walking. I found the uterus slightly retroflexed and its cavity of normal length.

Case 8.—Mrs. S., white, æt. 37 years; has had seven children followed by an induced abortion at two months two years ago. She was very ill after that and has never recovered from it. She is almost an invalid, having constant dull pains through pelvis that become lancinating after much exertion, requiring her to remain in bed. Menses profuse, and agonizing, lasting from five to ten days; complaints of neuralgic headaches, loss of appetite, constipation, and cutting pains when voiding urine. An examination revealed the uterus to be large, hard, and in normal position, but surrounded by a thickened vaginal roof. Any movement of uterus causes considerable pain and prostration. The galvanic current was applied as in the other cases and the nervousness following it was marked—so much so that the application was not extended beyond ten minutes. This occurred July 19 last; after she had rested about one-half hour, small pledgets of wool were applied against vaginal roof around the cervix. She did not return until August 1, at which time she claimed to feel better and that her bowels had been regular without medicines since her last visit. She was anxious to have the electric current re-applied, as some friend had had a "modern miracle" performed on her in New York by means of this agent. I did not like to repeat the experiment of two weeks ago, but as the patient was anxious to have it tried again I repeated it. This time the application was barely perceptible to patient, yet I had to discontinue it after about six

minutes on account of faintness and loss of motion in the lower extremities; her face was very pale and the pulse alarmingly weak. My faradic battery was convenient, and I applied the interrupted current along the spine for a few minutes. It was about an hour before she could walk. I treated this patient until the 2d of October, but did not again employ galvanism on her.

Case 9.—Mrs. A., 42 years old, consulted me July 2 last, regarding some pelvic trouble. She had had two children and a miscarriage at three months three years ago. Her trouble dated from the miscarriage. She suffers with pain in back and bearing down, poor appetite and nervousness. Menses profuse but regular, requiring her to remain in bed four of the six days every month. Has been under the care of a few specialists for a year. I found the vagina large and its walls relaxed—uterus enlarged, low and retroverted. It was almost immovable, very tender to touch, and seems to be imbedded into the thickened vaginal roof.

Galvanism three times a week for thirty minutes, each application being followed by a gradual pressure against the lower side of the fundus uteri by woolen tamponades. She expressed relief just after the first treatment. This method of treatment was pursued until the 9th of October, when the condition seemed normal. I made twenty-six applications of the galvanic current to this patient during the course of treatment.

I do not think much improvement occurred in case 3 during treatment by galvanism. She felt very well, but this was, I think, not due to improvement in the condition of the pelvic organs. Many women suffer a great deal from conditions about the same as this woman has, and I think she will sooner or later have a recurrence of pelvic pain and sensitiveness.

The result in case 5 was very pleasing to me, as I am very glad to save a woman her organs of reproduction whenever it is possible to do so.

If electricity is of much value in this class of cases, I think it has a great field in the future, and should be thoroughly tried before the ovaries and tubes are subjected to the knife.

I do not think much good will come from the use of electricity in large pelvic abscesses or in tumors of a cystic or malignant nature. But I think nearly all other diseases of the female pelvic viscera are amenable to its restorative influence. Even small abscesses and small cysts of these structures are, I believe, curable by the judicious application of this remedy. In many of the cases that have been reported as cures of ectopic gestation by electricity, the condition of the patient's pelvic organs previous to the discovery of the so-called pregnancy had not been known. The diagnosis in them was faulty, but the treatment perfectly satisfactory. It is not unfair to

assume that some of these cysts were not pregnant cysts, but arose in some other manner. Certainly no failure, even in quite inexperienced hands, of the electric current in such cases has ever, to my knowledge, been published.

1314 I St.

THE BACILLUS OF KOCH, AND ITS PATHOLOGICAL INFLUENCE.

Read before the Chicago Medical Society, February 18, 1889.

BY NORVAL H. PIERCE, M.D.,
OF CHICAGO.

It has taken practically over twenty-two years to develop the exact pathology of tuberculosis up to its present degree of completion. Since 1865, when Villemin proclaimed that by vaccination with tuberculous matter, an identical process like that of human tuberculosis could be brought forth in some of the lower animals, the contagious and infectious character of tuberculosis was partly believed or assumed by many. This, however, does not eclipse in the least the brilliancy of Robert Koch's discovery of the specific cause of tuberculosis, nor does it alter the fact that this same discovery is unquestionably the most significant advance made in pathological investigation. Before Koch's memorable communication to the Berlin Physiological Society, the "cheese infection theory," as explained by Buhl, and the weakly "diathesis theory," strove for supremacy as the disguise for real ignorance as to the true cause of the tubercular process.

The student who desires a plain and truthful statement of the condition of our knowledge of tuberculosis before Koch's investigations can do no better than read Klein's paper in the *Practitioner*, for August, 1881. The results of Koch's investigations have been confirmed by every investigator, great or small. The result of this knowledge is used in our every day practice as data upon which we base diagnosis and treatment. Every doubt is silenced as to the specific character of the microorganism named by Koch the bacillus tuberculosis.

Morphology.—The bacillus tuberculosis consists of a cell wall inclosing a protoplasmic body called mycoprotein. It belongs to the smallest and finest bacillary forms known to us. Only the bacillus of mice septicæmia surpasses it in fineness. The length of the single rod ranges from 1.5 to 3.5 μ .—equal to .25 to .75 the diameter of the red blood corpuscle, and there width is from one-fifth to one-sixth of their length. The most of them are equal to half the diameter of a colored blood corpuscle. The ends of these rods appear to be rounded. The bacilli arising from an artificial culture fluid are in general shorter and finer than those growing in the animal organism. The largest forms are found in the sputum of phthisis. The investigations of Raymond and Arthaud,

recently published in a monograph, would prove that the length of the bacillus tuberculosis is in direct ratio to the acuteness of the tubercular process, and it is my belief that the fineness of the bacilli and their straightness seem to bear the same relation. That is to say, the long forms are found in acute miliary tubercles, the shorter in those of a longer course, while in the very chronic the great majority of the microorganisms appear as mere cocci and the rods are thick and crooked. These facts are of very practical importance. In the interior of recent tubercular foci and in young artificial cultures the rods are straight. In the older artificial cultures and in phthisical sputum we meet, besides the nearly straight forms, a majority of slightly bent or curved forms. In still older cultures of low vitality, or in cultures that have been cut off from the air, we find the thick curved form still more numerous, and that the straight forms have nearly or quite disappeared. May we not, therefore, make the following query: Is not the thickening and bending but steps in the process of degeneration of the bacillus tuberculosis (*i. e.*, lessening virulence), and, if so, may we not use this fact as an aid in prognosis, and as a gauge, in given cases, as to the possible effect of therapeutics? They are all non-motil.

Artificial Cultivation.—Koch found that from his artificial nourishing grounds inoculated with tubercular matter, he could produce a growth of peculiar characteristics, consisting of the bacillus tuberculosis. They form dry, glossless, compact whitish scales, about the size of a poppy seed, which lie loosely on the upper surface of the desiccated blood serum. They never grow into the same, nor do they ever liquefy it. They do not grow into even the liquid expressed from the blood serum, but always upon its surface. All this is characteristic. No such appearance is presented by any other known bacterium. Their extraordinary slow growth is another characteristic. Not until after the eleventh day are they visible to the naked eye. Two weeks later they attain their maximum growth.

The culture of the bacillus is a most difficult task (of which, more anon), but when a pure culture is produced we may go on *ad infinitum*. If the serum, or the water expressed in dessication of the serum, grows dim, it is a certain sign that the culture is contaminated.

Examined under a low power, say 30–40 diam., these little elevations are found to consist of dainty spindle or "S" shaped colonies. Under a higher power, and after staining by Ehrlich's method, we find these colonies to consist of bacilli arranged parallel to each other, with their long axis corresponding to that of the colonies.

The substances used as media in which to cultivate the bacillus tuberculosis are not very numerous. Dessicated blood serum stands at the head of the list, for many reasons. Agar-agar is fair,

but we do not get the characteristic growths from it. Next in order of fitness we may mention meat-infusion, peptone-agar, liquid blood serum, and bouillon. In the latter, when placed in Erlenmeyer's bulbs, and vessels of like sort, the bacilli settle to the bottom, forming a delicate layer, resembling sand. Nocard and Roux found that the artificial growth of the bacillus tuberculosis is favored in a remarkable manner by the addition of glycerine to the culture medium. According to these experimenters 6 to 8 per cent. should be added to the serum, agar-agar, or gelatine. The addition of 20 per cent. of neutral peptone to the glycerine before its addition to the serum, and 50 per cent. of peptone to equal parts of bouillon, will be advantageous. Under these conditions the bacilli are more fertile and larger. According to Koch's method the bacillus tuberculosis grows only between 30–41 degrees, Cent. The raising or lowering of this temperature, even by so much as a fraction of a degree will hinder their development, so sensitive are they to deviations in temperature. With this fact in mind it is difficult to conceive of their undergoing any phase in their life history outside the human body. We may readily believe, too, that an accurately working thermostat is absolutely necessary. Equally important is the act of implantation. Besides the care required to prevent accidental contamination it is necessary that the inoculation material be placed on the surfaces of the serum in the daintiest and most cautious manner, so that after the inoculation the point of inoculation be almost invisible. Another item of success is the moist, succulent condition of the serum. When the latter becomes dry by evaporation, whether before inoculation, or during the time it is in the incubator the cultures fail regularly. To obviate this rubber caps are fitted over the cotton at the end of the tubes. Probably the salubrity of the glycerine-containing mediæ is due to some extent to the better retention of a moist condition in the upper strata from the presence of the glycerine.

Spore-Formation.—The phenomenon of spore-formation is still *sub judice*. A brief review of the various experiments and opinions would not be amiss here. We may take as the ripe bacilli those that present when stained a homogeneous appearance, without points of special tinctorial susceptibility. In others stained under precisely similar conditions, we find unstained spots that give them a beaded appearance. These unstained spots were regarded by Koch as endogenous spores. This opinion is still probable but not surely accepted. No one has as yet seen the germination of bacilli from these spots, nor has any one as yet been able to stain them. This, however, does not disprove Koch's opinion; on the contrary, in proof of it stands the great similarity of the endogenous spore formation of other bacteria, and also the great tenacity to life of the bacillus tuberculosis, the latter

being, indeed, especially characteristic of organisms of endogenous spore formation. Against this, again, mitigates Volsch's experiments, who, following the line marked out by Baumgarten, concluded that the bacillus tuberculosis has equal tenacity with or without these colorless spots.

We may ask, therefore, whether these unstained spots are really spores, or "vascular degeneration" (Baumgarten), such, for instance, as we see in the typhus bacillus; further, we find accompanying the bacillus tuberculosis, whether in the animal body or in pure cultivation on blood serum, round bodies which are comparatively quite readily stained and these have been regarded as possibly spores. Against this we have the following: If the *unstained* bacillus be examined in a weakly refracting media, we find spots of greater brightness within the body of the bacillus, and in the bacilli found in tubercular sputum, which are the very ones that show a great resistance to destructive agencies, are found the greatest number of glistening spots. It is, however, our opinion that the glistening spots are not spores, but vacuoles covered by part or a whole of the limiting membrane; that they are a portion of a process of degeneration; *i. e.*, occur at the time when the bacillus is threatened with destruction; but that they are connected in some way with spore formation; that they probably are the matrices out of which the spores have escaped. In support of this opinion, we observe:

1st. Spore formation occurs most excessively under conditions least favorable to growth (see experiments of Raymond and Arthaud in "*Études sur la Tuberculose*," Part I). 2d. Under the same conditions the occurrence of stained round bodies in the surrounding media with same color reaction as the bacillus, and an equally large number of unstained spots in the bodies of the bacilli. 3d. That these same round bodies are very often suspiciously close to the unstained spots in the body of the bacillus. 4th. That under certain unfavorable conditions the bacillus tuberculosis metamorphose into a coccus form, which I believe to be simply sporulation. And right here we may draw a practical conclusion. Numerous opponents to the bacillary origin of tubercular processes have held up the fact that the bacillus tuberculosis is not always found in so-called tubercular pus—quite justly, too. But this is because only spores are present, which, although less readily stained, will develop into the characteristic bacillary form under the proper conditions.

Staining Reaction.—The bacillus of Koch has tinctorial qualities that differentiate it from all other known bacilli excepting the bacillus lepre. It was Koch's original opinion that the bacillus tuberculosis alone could react to the alcoholic aniline solutions. This was found to be erroneous. The distinctive feature is their resistance to de-

colorizing agents, especially the mineral acids. We can best understand this phenomena by presupposing with Ehrlich that the bacillus tuberculosis possesses a tough capsule which, while resisting to some extent the entrance of the coloring matter, is impregnable to the decolorizing agent, thus distinguishing it from all known varieties of bacilla, with the exception above mentioned.

Agents Unfavorable and Destructive to Growth.

—The bacillus tuberculosis is quite able to endure the influence of any or all of the digestive secretions of the animal organism, and especially those of the stomach, as was proven by Falk in his artificial cultures and by the positive results obtained by Schell and Fischer in their feeding experiments. The tuberculosis bacillus has a very great resistance comparatively to the action of all disinfectants. Thus, the bacillus tuberculosis was destroyed only after twenty hours' contact with a 3 per cent. carbolic acid solution. This latter substance is therefore not to be relied upon, especially in the disinfection of tubercular sputum, in solutions of less than 5 to 10 per cent. Another fact of some importance is that corrosive sublimate is not applicable in disinfection of sputum; not because of a resistance on the part of the bacillus tuberculosis to this most powerful germicide, but because it *curd*s the sputum, thus materially hindering the complete mixture of the solution with all parts of the sputum. In pulverized sputum the bacilli were destroyed in twenty hours by 1:5,000 H_2Cl_2 . Baumgarten showed that a solution of 1:1,000 destroyed the spores in a very short time. Schell and Fischer found that besides carbolic acid and corrosive sublimate, absolute alcohol, sat. sol., salicylic acid, acetic acid, liq. ammoniæ caustica, sat. sol. of aniline in water, and the vapor of aniline oils generated at the temperature of the room would kill the bacillus after twenty hours. Practically we have no destructive agent that can be compared to heat, and especially moist heat, and this should be employed whenever possible.

To conclude this section we will discuss the question whether iodoform has any influence upon the growth of the tuberculosis bacillus or not. From the experiments of Baumgarten, Kunz, and the latest, of Rosing, we must doubt its power. The observations and deductions of Bruns and Nauwerck have slight weight as against these latter experiments. These surgeons claim that by the injection of iodoform into tubercular abscesses they were not only able to terminate the abscess, but to actually reduce the number of bacilli in the abscess walls. First, we must know that the number of bacilli in tubercular abscess walls are constantly changing. And, further, supposing that the number were reduced, we cannot say positively that this result was due to iodoform, as Bruns injected not pure iodoform, but a solution of it in alcohol and glycerine. We know positively that the former agent is a direct

poison to the bacillus tuberculosis. We know, too, that it is highly wrong and inconsistent to add glycerine to anything intended to hinder the growth of the tuberculosis bacillus. Further, we must consider, according to the researches of Baumgarten in the healing of tubercular abscesses, that the bacilli in them possess a relatively minor energy, an insignificant malignity; that the colonies are comparatively small, and that these colonies are few in number. The majority of these are in a good way to die off of their own accord, and it only requires the removal of the detritus, to prevent auto-inoculation, to bring about a cure.

Pathology.—The greater portion of the time allotted to the reading of this paper has already expired, and it seems like a pathological sacrilege to attempt a presentation of so great a subject in so short a time as remains. However, I will deal with it as best I can, though, as you must know, only cursorily.

The bacillus tuberculosis may gain an entrance into the human body in one of three ways: first, by respiration; second, by alimentation; and third, by inoculation. The subsequent pathological varieties will depend: 1, upon the conditions of the tissues of the individual; 2, the place of invasion; and 3, the vitality or degree of malignity of the bacilli invading.

1. The individual. There can be no doubt that there exists in some people a susceptibility to and in others an immunity from the invasion of the bacillus tuberculosis. The dog as a class enjoys an enviable immunity, the rabbit a susceptibility. This susceptibility may be inherited or acquired.

2. The place of invasion. It is a remarkable fact that no macroscopic changes occur in the great majority of cases at the place of primary invasion except in cases of inoculation. This is due, most likely, to the minor virulent condition of the bacilli. As was pointed out under the head of "Conditions Favorable and Unfavorable to the Development of the Bacillus Tuberculosis," it is extremely improbable that they can develop outside the animal body, on account of their exquisite sensitiveness to temperature change, but disseminate themselves outside the body mainly as spores. In the majority of cases the invading bacilli are in their spore stage and develop into ripe bacilli after they have secured a suitable nidus in the body. Again, the normal secretion, at least of the alimentary tract, while not destructive, has a deleterious effect upon their virulence. An entrance gained, however, they are taken by the lymphatics either to the thoracic duct, and there poured into the blood, or they gain lodgment in the lymphatic system before this takes place and multiply, and the tubercular process begins.

Whether they develop at the point of primary invasion, which is rare, or gain entrance into the

lymphatic or circulatory system before development, the results are the same—a more or less acute or chronic tubercular process. To be sure, the pathology of the resulting tubercular process will differ according to the mode of infection. Thus, in hæmatogenous invasion of the lung or an invasion by bacilli circulating in the blood, we have as a result the small or miliary tubercular process scattered throughout the lung parenchyma, one alveolus at a time becoming involved. This is easy to understand. When, however, a number of fully developed and virile bacilli are inhaled and they attack the epithelium of the whole lobule or lobules at once, the result is the cheesy lobular pneumonia. This process may be brought about in rabbits by intra-tracheal injection of pure culture bacilli. The identity of this process with a true tubercular process is not, I believe, sufficiently recognized in this country. The rapidity with which the bacilli are taken up by the lymphatics is astonishing. Three days after the inoculation of the anterior chamber of the eye of a rabbit they have already forced themselves into the auricular lymph glands. And in spite of the thorough removal of the affected eye at this early date the animal died of general tuberculosis.

When the lungs and kidneys are examined twenty-four or forty-eight hours after an intravenous injection of bacilli, it is only by the most thorough search that here and there a tubercle bacillus can be found. Yet, it is proven that fourteen days or three weeks later countless numbers may be found in the above-named organs, proving that a number are retained by these organs, and that they offer a favorable ground for their growth. It is wondered at why, in lungs and kidneys, in spite of a relatively small retention of bacilli, larger and more numerous foci are developed than in spleen, liver and bone. We may presume that the different organs do not furnish an equally good nourishing ground for the bacilli, that the lungs and kidneys furnish a more salubrious resting place than the bone and liver, a presumption supported by many analogies.

The histogenesis of tuberculosis cannot be dealt with here. We will content ourselves with studying that pathognomonic iota wrought by the bacillus tuberculosis—the miliary tubercle.

It is impossible to give a definite size to the tubercle. In one case it is invisible to the naked eye, in another it may be as large as a pea. When visible to the naked eye they appear as small round, more or less opaque, pearly-white nodules. When occurring in an organ that tends to retract when cut the tubercle stands out in bold relief.

Histologically the tubercle consists of a giant cell around which are arranged the epithelioid cells, smaller than the giant cells, around which in turn are grouped the lymphoid cells. The whole is most frequently held together by a reti-

culum. The absence of blood-vessels is characteristic of the tubercle. The lymphoid bodies are the first to appear at the point of attack of the bacillus tuberculosis. Their nucleus occupies nearly all their body, leaving only a small margin of protoplasm. On the sixth day after the inoculation of animals the epithelioid cells appear—the first distinctive step in the tubercular process. They appear at the point where the tuberculous bacilli are most numerous. Lastly the giant cells are formed, having their nuclei, ten to a hundred, *arranged in the periphery of the cell*. The epithelioid cells originate from the fixed epithelium and endothelium of the tissue involved. The giant cells are caused, most likely, by an inhibition of the normal cell divisions, the cell increasing in size notwithstanding. Between the cells and within them are grouped the bacilli. Twenty may be counted within a single section of a giant cell. The trabeculum is derived from the preëxisting connective tissue elements; changed, of course, by the new order of things. The roundness of the tubercle may be explained thus: In the beginning of the tubercle formation the cell-growth is greater at the centre of the bacilli colony than at the periphery and, as there is a pressure exerted upon the centre by the periphery, a rounding up, as it were, results.

Regarding the uncertainty of the presence of the giant cells in tubercles we would say that their absence is comparatively very rare. If microorganisms are not necessary in every case to the development of giant cells, we know that the bacillus tuberculosis possesses this capability to a supreme degree. Yet, like many other things in nature, they may fail.

The tubercles may undergo: 1, reformation; 2, calcification; 3, caseation; 4, liquefaction; 5, supuration; 6, ulceration. Of these we will only speak of coagulative necrosis and suppuration. We cannot regard the caseous process (coagulative necrosis), as it occurs in the tubercle, in the sense used by Weigert in describing those processes taking place by reason of simple arrested circulation or nutrition; as, for instance, in a non-infected infarct. We must look to the bacillus for a part of the change wrought. True, lack of nutrition has something to do with it, but the digestive power of the bacillus has more. And it may be thus looked upon as characteristic of the tubercular process, that no formation *so small in size* as a tubercle undergoes such a change.

Suppuration.—The bacillus tuberculosis never forms pus. Only when the so-called tubercular granulation tissue has become infected with the staphylococcus or streptococcus can true pus be formed. The contents of a purely tuberculous abscess contains only a few round cells, but an amorphous shreddy material, the result of the digestive power of the ptomaines from the bacillus tuberculosis upon the granulation tissue.

THE ETIOLOGY, PATHOLOGY AND TREATMENT OF ACUTE CATARRH OF THE UPPER AIR PASSAGES.

Read before the American Rhinological Association, September 12, 1888.

BY J. G. CARPENTER, M.D.,
OF STANFORD, KY.

The etiology of acute catarrh is either local or exciting, predisposing or constitutional: the use of tobacco, occupations attended with much dust, smoke, irritating gases, excessive moisture or dryness of the atmosphere, sudden changes of atmospheric temperature, as from a dry warm to damp or damp and cold weather, or from a warm room to the cold air without being sufficiently protected with wraps, getting the feet wet, standing or sitting for some time on a cold surface. A very pernicious habit is wetting the head, which is practiced daily by young ladies, and also by mothers and nurses, who wet the hair and scalp of children one or more times daily and thus develop acute or subacute catarrh, and the child is seldom over one attack before another begins; finally chronic catarrh of the upper air passages is established. Exposure to the night air without extra wraps is one of the most frequent causes of acute catarrh. Wearing damp clothes, changing beds and sleeping in rooms without fire (when not accustomed to the latter), exposure to currents of air, insufficient clothing, substituting light and thin goods for heavy and warm ones, changing boots for shoes or slippers, going without collar, cravat or cuffs, sitting up late at night and allowing the room to cool before retiring, facing the wind in traveling and not having the nose, mouth, throat and chest protected with extra wraps, removing the clothes and exposing the body in an almost nude state for half an hour or more before retiring, as many ladies do, are prevalent factors in the production of acute catarrh.

Mothers and nurses often develop acute inflammation of the upper air passages by getting up at night with children or patients in the cold air and not clothed properly; the body is not kept at the same temperature as when in bed, the consequence is that the integument is quickly chilled, its action suppressed, and through reflex irritation the mucous membrane of the upper air passages becomes congested or inflamed, as it is generally the weakest point, and most subject to irritation.

Too much clothing, as wearing sealskin sacques, chinchilla ulsters, fur collars and overshoes, on improper occasions as in pleasant weather, and not removing them on entering the house, church, theatre, or when making social calls, is equally as prone to develop acute catarrhal inflammation as insufficient clothing and undue exposure to inclement weather. The body should be clothed so as not to cause perspiration nor chilling.¹

¹ It is said that sealskin sacques have in a given time caused more deaths than small-pox in New York (Bosworth).

Two barbarous customs are: first, the kind of hats or bonnets worn by women, which give no protection to the head; second, the manner in which boys and girls are dressed by the affluent, viz.: overclothing the trunk and head and allowing the limbs to be in an almost nude state, especially the knees, legs and feet, even in the coldest weather.

One of the most, if not the most prolific causes of catarrhal inflammation of the upper air passages is the treatment given infants immediately after birth. Generally the first thing that happens to the babe after the establishment of respiration is a cold in the head; or, as the nurse would say, "the little thing has the snuffles." It should be the exception and not the rule for infants to acquire a rhinitis shortly after birth from unnecessary exposure, chilling and sudden radiation of heat and evaporation of the body. It is quite common for the specialist to hear, "Doctor, my child has had a cold since its birth." The infant, before nor after severing the cord, should not be exposed, but wrapped in flannel of several layers in thickness. If very feeble, the cord should not be severed until pulsation has ceased, then artificial heat applied, the skin anointed with vaseline and the clothes quickly adjusted, an extra wrap applied and the babe placed at the mother's breast. If necessary, in the fall, winter or spring, artificial heat should be used. At the time of birth the temperature of the room, for the benefit of the babe, should range from 85° to 100° F. A sudden change of temperature from 20° to 60° F., from hot to cold, would injuriously affect a robust adult, nude or unprotected; how much greater must be the change and shock in the newly born babe, born and washed and dressed in a cold room and unnecessarily exposed. Many affections of the nose, throat, ears, eyes, trachea and bronchi could be avoided in children subsequent to birth if the accoucheur would use the proper precautions, and give the appropriate directions.

Constitutional causes of acute catarrh are rheumatism, malaria, measles, scarlatina, small-pox, diphtheria, uterine affections, especially endocervical metritis, neurasthenia. Excessive fatigue, either mental or physical, by impairing the general health, places the system in a condition favorable to acquiring catarrh of the upper air passages.

Pathology of Acute Catarrh.—The mucous membrane, the blood-vessels, nerves, lymphatics of the rhino-pharyngeal cavities, supply or communicate with those of the eye, frontal, ethmoid and sphenoidal sinuses, the antrum, maxillars, the middle ear, lower pharynx, the tonsils, buccal cavity, larynx, trachea, bronchi and lungs; consequently an irritation or inflammation of the superior respiratory tract is easily extended to these parts by reflex action or continuity of tissue.

The force of irritation and inflammation in acute catarrh of the upper air passages may be

confined to the nares *per se*, the naso-pharyngeal chambers, or to the latter and the ethmoidal, sphenoidal and frontal sinuses and eyes, middle ears and antrum, or to the pharyngo-laryngeal cavities and trachea, and as the inflammation of one organ or region is of greater intensity and duration and predominates over the others, it is designated by that name, as rhinitis, rhino-pharyngitis, laryngitis, etc. Acute and subacute catarrh may end in resolution or in the chronic. When a chronic naso-pharyngitis is once established, it is quite easy to develop an otitis media, a conjunctivitis, a laryngitis, or rhinitis frontalis or ethmoiditis, sphenoiditis, or a tonsillitis. (The writer believes that catarrh of the upper air passages is the predisposing cause of phthisis in many cases—yes, in the majority of cases, it might be stated without exaggeration. Feebleness of constitution is inherited from consumptive parents, but consumption is not, it is acquired. "The discharge or secretion of catarrhal inflammation and the lymph channels afford the most favorable soil and habitat for the growth and reproduction of the bacillus tuberculosis," and when the catarrhal secretions contain bacilli they are capable of affecting healthy persons when dried, pulverized, and blown by the air and respired; hence, to avoid phthisis pulmonalis, keep the constitution normal, the upper respiratory passages healthy, and prevent a suitable soil for the development and reproduction of the bacillus tuberculosis. In every case of phthisis pulmonalis the writer has observed, rhino-pharyngeal catarrh, in one or more of its stages, was present.)

For convenience and perspicuity acute catarrh may be divided into three stages. 1, the dry or congestive; 2, the moist or liquefactive; 3, the muco-purulent.

In the first stage there is an irritation of the mucous lining directly or reflexly; following this, there is dilatation of the blood-vessels with hyperæmia, redness, heat, tumefaction, and pain from pressure on the terminal ends of the nerves. Rhinoscopic examination shows a red or dark red, dry, congested, swollen appearance of the mucous lining, the blood-vessels are distended, enlarged, elongated and tortuous, and the lining often quite cedematous in those parts where it is loosely attached, or where it lies upon loose areolar tissue beneath.

Second Stage.—In addition to the first stage there are the following abnormal conditions, transudation of serum, diapodeses of the white corpuscles, infiltration of the connective tissue, cell proliferation, organization of lymph. The walls of the mucous follicles are swollen, they are distended, abnormally active, and throw out an abundance of mucus upon the surface of the mucous membrane. The mucous and submucous areolar tissue are infiltrated, thickened and cedematous. On rhinoscopic examination the dry, red,

glazed appearance has given way to a moist, juicy state of the surface: irregular elevations are seen corresponding to the distended crypts. There may also be infiltration and œdema of the turbinated processes and septum, causing nasal occlusion, enlargement and tenderness of the anterior cervical and maxillary glands, uvula, palate and tonsils.

The third stage is a continuation of the second, and is diagnosticated by a denudation or an erosion of the epithelial layer, leaving a raw surface, especially where there is much desquamation; supplementing this is a muco-purulent or a purulent secretion. Should resolution take place, the inflammatory products are absorbed, the blood-vessels contract to their normal size, excessive secretion is arrested, and the mucous surface presents its former healthy appearance.

On microscopic examination the mucous secretion contains tessellated and squamous epithelium, also columnar ciliated epithelium. The secretion from the upper pharynx is columnar ciliated epithelium; from the lower squamous epithelium; the epithelium of larynx below the superior vocal cords is columnar ciliated, above this point squamous; that of the trachea is also columnar ciliated. There are in addition, in the second state, mucus, white and red blood corpuscles, and pus corpuscles in the third stage.

Should acute catarrh not end in resolution, but in the chronic, there are developed in the mucous and submucous or connective tissue new layers of connective tissue elements. In the epithelial, there is an increased activity of cell growth by which it becomes abnormally thickened and hypertrophied, the glandular tissue is also involved, but to a limited extent. In the nasal cavities, the thickening is a regular and uniform hypertrophy, but appears irregular and nodular on the mucous surface. The hypertrophy is developed to its greatest extent in the turbinated bones; the inferior more than the middle, the latter more than the superior. The meatuses and septum are also affected by the infiltration.

Atrophic catarrh usually follows the hypertrophic and is generally late in developing, but may occur early, from recurrence of the acute or sub-acute catarrh, by which a deposition of lymph into the submucous connective tissue around the glands and follicles results, causing pressure on their orifices preventing the escape of mucus. After this pressure has existed for some time atrophy of the glandular and follicular tissue takes place.

Boston, Mass., Feb. 14, 1888, with symptoms of ulcerative colitis. He had had diarrhœa for two years, the discharges being watery and occasionally mixed with mucus and blood. There was tenderness on pressure over the entire course of the colon, notably the ascending portion. Examination of the rectum with the speculum gave a negative result. Patient's appetite was poor and his appearance anæmic. Ordered opii pulv. and bismuth subnit., milk diet, and rest in bed. Under this treatment there was some improvement of the intestinal symptoms.

April 4th. Had a chill, followed by fever and sweating. Had been complaining of pain in right hypochondrium for several days previously. From this time patient had irregular chills and sweats, with increased temperature. Tenderness developed over the hepatic region, and the area of hepatic dulness was found to be abnormal in extent, reaching from just below the nipple to a point 3 centimetres below the border of the ribs. From the symptoms and history a probable diagnosis of abscess of the liver was made, and on April 11th the aspirator was introduced in the eighth intercostal space and 100 cc. of viscid, blood-stained pus evacuated.

April 15th. 300 cc. of pus removed by the aspirator; pain relieved by the operation and patient slept better.

April 20th. 500 cc. of pus removed by the aspirator. As the abscess was evidently enlarging, it was determined to resort to a more radical operation.

On April 22d an incision was made in the eighth intercostal space, between the axillary and mammillary lines, and extending down to the surface of the liver. The chest cavity was obliterated at this point, owing to adhesion of the costal and diaphragmatic pleura. As no fluctuation could be detected, the incision was continued into the tissue of the gland, in the direction of the previous punctures, and the abscess cavity entered about 3 centimetres below the surface of the organ. The opening was enlarged by the forceps and rather more than 1000 cc. of reddish, grumous pus evacuated. The cavity was irrigated with 1:20,000 warm corrosive sublimate solution, a large drainage tube introduced, a dressing of absorbent cotton, wrung out of sublimate solution, applied and the whole covered by a large pad of oakum secured by a bandage. Cocaine was used as a local anæsthetic.

Next morning, April 23d, the dressings were found saturated with pus and bile, and patient was decidedly jaundiced. The abscess cavity was irrigated with solution of bichloride of mercury, 1:20,000, but this caused so much pain and symptoms of collapse that it was never repeated. For the following notes I am indebted to Assistant-Surgeon G. T. Vaughan, M. H. S., who at this time took charge of the case.

ABSCESS OF LIVER: RECOVERY.

BY L. L. WILLIAMS, M.D.,

PASSED ASSISTANT-SURGEON, U. S. MARINE-HOSPITAL SERVICE.

C. B., seaman, aged 36 years, native of Maine, was admitted to the U. S. Marine Hospital, at

"The abscess continued to discharge freely through the drainage tube, gradually decreasing in quantity, till the 12th of May. On this day, as there had been only a small amount of serum on the dressing for two or three days, the tube was removed.

"Patient's condition steadily improved from opening of the abscess. Temperature 36.8°C. , in morning, 37°C. , in evening—once only reaching 38°C.

"Discharged, recovered and seaworthy, June 4th, 1888."

CLINICAL AND EXPERIMENTAL RESEARCHES UPON THE PATHOGENESIS OF FEVER AND THE PATHOGENIC ACTION OF SOLUBLE FERMENTS.¹

A Paper presented before the Académie de Médecine of Paris.

BY M. ROUSSY.

[Translated from *La Semaine Médicale* by ARCHIBALD CHURCH, M.D., of Chicago.]

In bringing forward to-day the second part of the investigations I have undertaken in regard to the pathogenesis of fever, I will recall that M. Hayem three weeks ago presented to the Academy in my name a new chemical substance, pyretogenine, isolated from a microorganism and possessing the singular property, in minute doses, of determining intense and typical attacks of fever.

In the paper describing at length the physiological effects produced by this substance, I announced that I had also experimented with other substances which I proposed to range under the denomination of calorigenes or thermogenes, because they only determined a feeble elevation of temperature without producing the other perturbations characteristic of fever. Further, I announced the existence of frigorigenes, chemical substances of microbial origin, among which was one more energetic than the others that I designated frigorigenine.

I gave in my first paper neither the name of the microorganism which had furnished the pyretogenine nor the process which I had employed in its extraction, but promised to make both known in a subsequent communication, which to-day I submit in two parts. In the first I make known my chemical and experimental investigations of the pathogenesis of fever, and in the second I bring forward a general theory as to the nature and the physiological and pathogenic rôles of diastases or soluble ferments.

First as to the clinical observations. I noted intense fever occurring in adults and children after overeating, after the ingestion of stale beer, of

tainted meat, of stagnant water containing dead leaves, hay or flax. The abrupt appearance of this fever and its more or less rapid and unexpected subsidence led me to the hypothesis that the cause was the presence in the organism rather of soluble substances than of microorganisms.

With the purpose of verifying this hypothesis I have experimented on rabbits and dogs with substances analogous to those which seemed to me to have produced the fever observed in man. These investigations, extending over more than three years and embracing more than 400 varied experiments, have led me to formulate the following conclusions:

1. Subcutaneous and intravenous injections of stale beer, of macerations of hay, of tainted meat, etc., always determine fever in dogs and rabbits.

2. This fever appears very soon after the injection and shortly attains a temperature of 42°C. In these cases the injection produces an infectious disease which is generally followed by death. The intensity and rapidity which characterize this fever lead me to think that it should be attributed more to the soluble chemical substances than to the mechanical action of the microorganisms which are contained in the injected liquids.

3. Intra-stomachal injections produce but little fever in rabbits and are without effect upon dogs, leading to the thought that the soluble chemical substances are modified or destroyed in the intestine or in the organs they must traverse to enter the system, and possibly in dogs may not be absorbed at all.

Second, as to the frigorigenes or algogenes of microbial origin. These chemical substances may be encountered in animal matter destroyed by fermentation. They are susceptible of extraction by ether, chloroform and alcohol.

The substance extracted by ether possesses the most energetic frigorigenic properties. It produces a temperature fall of 4°C. It seems to have a tendency to crystallize. It acts as a base in the presence of the ordinary reactive agents of alkaloids. For these reasons it seems proper to distinguish it by the special name of frigorigenine or algogenine.

The production of frigorigenic substances appears to be subject to particular conditions of animal fermentation by microbial action, for one does not encounter these products in all animal matters undergoing fermentation, or at least in all stages of that fermentation.

The existence of these substances being absolutely certain, they should be sought in the cultures of cholera bacillus and in patients presenting temperature below the normal.

In experimenting with the putrid liquids cited above I have been particularly struck, in many instances, by the pyretogenic power of stale beer. Examining more closely the composition of this liquid I found in it a large number of yeast cell-

¹This article takes up the very interesting subject of disease, and particularly fevers, being produced by the chemical products of bacteria rather than by the mechanical action of the bacteria themselves, and seems to point the way towards a more intimate knowledge of pathology.

ules. In using the stale beer I have then, in short, merely employed a maceration of yeast cellules. I was thus led very naturally to attribute the pyretogenic properties of the liquid to the yeast spores which it contained in such great abundance.

Such is the starting-point of all the experiments I have subsequently made with the soluble products of the yeast cellules, and which have given me such satisfactory results.

Third. The water used to wash the living spores of beer yeast possesses energetic pyretogenous properties which may not be attributed to the mechanical action of the microorganisms, and which are due to the soluble chemical substances held in solution. These substances are nearly entirely retained in the pores of the finest mineral filter, and filtration by means of such a filter is an undesirable proceeding in making a study of soluble substances. Solutions of chlorate of strychnia perfectly made lose their toxic properties by passing through a mineral filter, and accurate weighing shows that 70 per cent. of the strychnine remains in the filter. The same is true of curare. The best means of studying chemical substances in solution is to isolate them by chemical processes. The soluble chemical substances which impart the pyretogenic properties to the water which has been used to wash the cellules of yeast are the direct products of the microorganisms and constitute the results of their processes of secretion or excretion. These substances take on much more energetic pyretogenous properties when the spores are reduced in a neutral medium, such as distilled water, to a condition of autophagia. They may be extracted in sufficiently large quantity for separate study by treating a small quantity of sterilized distilled water containing several kilograms of spores with a large quantity of strong alcohol. Owing to their unequal solubility in water, alcohol, etc., they may be obtained separately and in a pure form. In this manner I have succeeded in isolating four substances, of which three are crystallized, and the fourth composed of fine homogeneous granules.

The most active of the substances elaborated by the yeast cellules, and which most influences the process of animal calorification, is the one presenting the granular form. Its pyretogenic energy is surprising. A few tenths of a milligram to the kilogram of animal weight rapidly produces in the dog an access of most intense and typical fever. This access of fever describes its evolution in nine or ten hours and in three phases, during the course of which all the functional troubles characterizing an access of paludal fever manifest themselves. By reason of its physiological potency, so powerful and so well defined; by reason also of its chemical properties, I think one could not do better than to designate this singular substance under the name of pyretogenine.

Among other chemical properties it has the power of breaking cane sugar into glucose and levulose. A minute quantity suffices to transform a relatively enormous amount of sugar. It acts, then, exactly as a diastase, and conducts itself toward reagents as a base.

I now come to the second part of my task, the general theory of the nature and the physiological and pathogenic rôles of the diastases or soluble ferments. Pyretogenine is, as we have seen, one of these soluble ferments which one invariably finds where cellules, without being destroyed, and whose action has hitherto been mysterious, seem to break up the organic molecules merely by their presence. Diastases appear to reduce organic material by chemical processes more or less analogous to those which take place in the reactions of sodium, potassium or baryta upon fats or upon albumen. Yet it is not absolutely known by virtue of what property these singular ferments act.

Now, in presence of the clearly toxic properties of pyretogenine, may one not suppose that the other diastases have similar properties, and that they reduce organic matter precisely because of this toxicity. This is a new and positive fact hitherto unknown to science, and seems to me to be great with consequences for general pathology. Its bearing cannot be mistaken by any one. To generalize: all spores, in short, all microorganisms, elaborate diastases or soluble ferments which they employ to attack and transform material either without or within the confines of their proper substances, and these ferments often have a most surprising chemical energy, liquefying the most resisting and apparently unattackable substances.

Three years ago nearly all microbiologists were occupied merely with the pathogenic rôle played by microbes considered in themselves the active elements. I would call attention particularly to the necessity of studying the pathogenic action of the chemical substances which are the results of their life-processes.

MEDICAL PROGRESS.

THE TREATMENT OF LOCOMOTOR ATAXY BY SUSPENSION.¹—Under the above title, Dr. A. de Watteville has translated and edited the paper in which Professor Charcot describes the method of treatment of locomotor ataxy, and other spinal diseases, at the Salpêtrière, of which some account was first given in our pages in the letters on "Medical Paris of To-day." So much interest has been shown by our readers in this subject, and so many inquiries have been received, that

¹ Translated from the French of Professor Charcot, and edited by A. de Watteville, M.A., M.D., B.Sc., Physician to the Electro-Therapeutical Department of St. Mary's Hospital. With 4 illustrations and notes. London: D. Stott, 370, Oxford Street.

we publish subjoined that part of Dr. de Watteville's pamphlet which relates to the practice of the methods of treatment and its details. He writes as follows :

As was to be expected, some persons have already endeavored to improve upon the method, such as, for instance, by advising the adjunction of plaster spinal supports that are, to say the least of them, entirely superfluous under the circumstances, at any rate in cases of true ataxy.

Professor Charcot has thought it advisable, therefore, to publish the following technical details, suggested by an experience acquired in the course of over 800 suspensions, practiced under the supervision of his chief assistant, in the cases of forty patients. For, though the operation is, in itself, very simple indeed, it yet requires a certain skill that is more easily acquired with the assistance of definite rules, than by the sole experience of entirely original experiments.

The apparatus used is that contrived by Sayre, of New York, for the application of plaster jackets used in cases of spinal deviation. Though pretty extensively known, we shall give a short description of the form of it used in Professor Charcot's *clinique*. A transverse piece of iron, about eighteen inches in length, is suspended by means of a central ring to the pulleys which are used to lift the patient from the ground. Each extremity of the bar ends in a hook, intended to support the ring, which carries the straps intended to give support under the armpits. Several notches on the upper aspect of the bar serve to fix the rings from which hangs the head-piece. The latter consists mainly of two broad strips of leather, elongated oval in shape, moulded to receive the chin and the occiput respectively. These are connected above with the rings just mentioned, and are held in position by means of a strap sewn to the posterior flap, and fixed to buckles carried by the chin-piece, so as to hold the head-support in place when the patient is suspended.

Much depends upon this strap, which must be tightened enough to prevent any slipping, and yet not sufficiently to cause compression of the blood-vessels of the neck, and thereby unpleasant head-symptoms. It must be provided with a sufficient number of holes to accommodate itself to the varying thickness of the neck among those to be suspended. In case of need, which is not often, a soft body, such as lint or cotton-wool, may be inserted so as to prevent undue pressure of the strap or broad pieces upon the skin. It is necessary to exercise much care in fitting the head-piece and padding, so as to suit the peculiarities of each subject. The size of the head determines the notches into which the rings of the head-piece are to be fixed, the larger the head the wider apart they must be, of course.

When the head is duly disposed of, the shoulder-

pieces are slipped under the armpits. Though they may appear of minor importance, they really play the part of regulators during the period of suspension. For it is necessary that whilst lifted off the ground the patient should not be entirely supported by the head-piece, for then the traction would become, in some cases at least, absolutely intolerable. Though the weight of the body must be distributed upon other points, this additional support must not be so effectual as to prevent as complete an extension of the spinal column as possible.

The shoulder-pieces consist of elongated cylindrical padded cushions, terminating in straps provided with a series of holes so as to suit, by appropriate lengthening or shortening, the requirements of each patient. This adaptation is very important; for if too short, the shoulder-pieces exercise such a pressure upon the axillary vessels and nerves as to compel the operator to bring the suspension to an abrupt and premature termination. If, on the other hand, they are too long, the traction on the structures of the neck may become too painful to be tolerated, and interfere likewise with the treatment.

Careful trials are necessary to determine the exact length of the several straps; but after three or four operations it becomes easy to decide the arrangement suitable for each case.

When all is ready the physician orders his assistant—with some practice he may do without one—to apply traction upon the core, very gently and slowly, so as to avoid jerks, and to accustom gradually the muscles and ligaments to the unusual tension to which they are going to be submitted. The patient is to be cautioned not to make any movements whatever whilst he feels himself being lifted off the ground, for they would give rise to unpleasant lateral and rotatory displacements.

As soon as the toes cease to touch the floor, the operator holds the patient lightly, so as to check any oscillation or torsion of the cords, and carefully watches the number of seconds that elapse, so as to regulate minutely the length of each suspension. During this period the patient is made, at intervals of fifteen or twenty seconds, to raise his arms laterally away from the body, so as to transfer more weight upon the head-piece, and so render the traction upon, and elongation of, the vertebral column still more complete, as complete as is tolerated by each individual. Much care and vigilance is to be bestowed upon the proper performance of these abductions of the arms, both by patient and physician. As a rule, the longest time of suspension must not go beyond four minutes, three minutes being taken as the average duration. Half a minute is enough at the outset, the maximum being gradually reached during the first six or eight applications of the treatment.

Here again it is essential to take into account certain individual susceptibilities or physical peculiarities, among which stands foremost the body-weight of the patient; for whilst a person weighing from about 130 to 150 pounds may be suspended forthwith during two minutes or more, the case is quite different in the case of those whose weight reaches 180 pounds or more. In the latter, the tension to which the structures of the neck are subjected may become very severe and painful, and be felt sometimes for a whole day afterwards—an occurrence which must be avoided if the treatment is to be correctly carried out.

It is well to note that certain patients have such a wish—a very natural wish—to get better, that they think themselves bound to stand any amount of pain without complaining; but this circumstance is positively detrimental to the success of the treatment, which must be accompanied with but trifling discomfort at the most, without real pain or fatigue, lest it should defeat its own ends.

The maximum length of the suspension must, therefore, be suited to the requirements of each patient; it is obvious that in the case of heavy persons the effect on the spine must be very thorough and effective, owing to the greater traction to which it is subjected. Suspension must not be carried out oftener than once on alternate days, otherwise it may become more hurtful than beneficial. The time of the day is indifferent, but regularity in the operations is to be observed.

When the full time has elapsed the operator very gradually lets the rope loose, so as to avoid every trace of jerking during the descent. The patient is to be supported whilst being freed from the apparatus, and made to rest awhile in an arm-chair brought near for the purpose.

The patient, before the operation, should divest himself from his coat, so as to give freedom to the arms, and his neck must be free from any pressure from the collar, so as to avoid any trouble or discomfort from compression about the neck. Sayre's original apparatus usually comprises a movable tripod, to the top of which the upper pulleys are fastened by means of a hook. This tripod is not to be used for suspending ataxics, who, being often deficient in power to sustain their equilibrium, are apt to seize convulsively its legs in order to steady themselves, and in so doing would knock down the whole apparatus, and injure themselves and the bystanders. The suspensory apparatus must be fixed to an iron ring firmly screwed in the ceiling.

"The results obtained by Professors Eulenberg and Mendel at the Berlin Clinic for Nervous Disease in the cases of twenty ataxics, fully confirm, so far as can be judged from the comparatively

recent introduction of the new treatment, the encouraging outlook sketched out in Professor Charcot's communications. The improvement observed bears chiefly upon the walking power, the equilibration, the lightning pains, and, in a few cases, the bladder troubles. Moreover, no bad symptom whatever has been observed, even in the case of the female patients who are undergoing the regular course of suspensions. At the same time, the most sanguine observer must acknowledge that it is entirely premature to come to any definite conclusions upon a point of such deep perplexity as the question of the possibility of absolute cure in locomotor ataxy. Physician and patient alike must beware from falling into the temptation of conceiving exaggerated hopes as to the final results, in the presence even of effects as incontrovertible as those testified by so many able and critical observers."—*British Medical Journal*, March 9, 1889.

PUERPERAL FEVERS AND SEPTICÆMIA.—We copy the following from a letter by ROBERT BARNES, M.D., in the *British Medical Journal*, March 16, 1889.

By the term "puerperal fever," we must understand "fever in a puerpera."

As fevers of various kinds may assail non-puerperal persons, so they may assail puerperæ. We must, therefore, abandon the vain attempt to find one definite puerperal fever, and we must recognize the clinical truth that there are puerperal fevers.

There is, however, one constant underlying condition of all the puerperal fevers; that is, the puerperal constitution. This forms the soil in which all the disturbing influences work, in which noxious matters, from whatever source, internal or external, germinate, and which, without always destroying the individual properties of the foreign poisons, imparts to all some common features. It is also highly probable that under the mutual reactions of ingested poison and the puerperal constitution, new innominate poisons may be engendered.

The puerperal fevers may be classified under the two great divisions of autogenetic and heterogenetic. *a.* The autogenetic fevers are 1, the simple excretory puerperal fever, the result of endo-sepsis, or the arrest of the excretion of waste stuff of involution; it is especially prone to arise in damp cold weather. This form complicates all other fevers, even the septicæmic form; 2, the fever resulting from absorption of foul stuff from the parturient canal, either from the unbroken mucous surface, or by the open mouths of vessels, or from traumatic surfaces; this is autoseptic. This form is also likely to complicate other fevers; 3, this, the proper septicæmic puerperal fever, is revealed under the forms of metritis, peritonitis, pelvic cellulitis,

thrombosis, and general toxæmia. *b.* The heterogenetic fevers are due to a poison from without. These may be divided into 1, the cadaveric poison, which wrought such havoc before the days of Semmelweis, the septic stuff from other puerperæ, animal poisons of obscure origin; and 2, the known zymotic poisons, as small-pox, scarlatina, typhoid, diphtheria, erysipelas.

All the various modes of infection recognized as acting in non-puerperal subjects act in the puerpera; but she is especially open to invasion by direct inoculation by the parturient tract, and empoisonment by all routes is greatly favored by the peculiar activity of the absorptive function.

Can any one of the foregoing propositions be disputed? Are they not the direct expression of precise objective clinical observation, freed from the bias of subjective idols? What then becomes of the dogma of septicæmia pure and simple?

I have shown that this dogma is not only false, but therefore dangerous. To see in septicæmia the only evil is to fix all therapeutical energy upon what is commonly understood as antiseptic treatment. This is the course advocated by the more earnest of the septicæmic school. Without affirming that they recognize no other remedies, it is not too much to say that they carry the practice of antiseptic irrigations to an irrational extreme, and to the comparative neglect of other important indications. They assume, on the other hand, that those who deny the exclusive dogma of septicæmia are stricken with therapeutical impotence. "The doctrine of antogenesis," exclaims Parvin, "is a confession of ignorance, the creed of fatalism, the cry of despair. . . the very pessimism of obstetric medicine." Big words, full of sound, and little else! The truth is, that those who take a broad, comprehensive catholic view of the many factors in the etiology, and constitution of puerperal fevers, take also a broader, more philosophical, and more rational grasp of the principles of treatment, and especially of prophylaxis. I hope I may be pardoned for saying that in no text-book of obstetrics is antiseptic treatment more carefully described than in that which bears my name.

I may fitly conclude with citing from a paper on "Antiseptic Midwifery and Septicæmia in Midwifery." "So far as antiseptic appliances are concerned, they can strictly only be regarded as subsidiary means in the carrying out of the great principle that lies at the bottom of all good obstetric practice—namely, to screen the lying-in women from those poisons and other noxious influences which threaten her from within and from without. It is not, therefore, desirable to devote special or separate attention to what, after all, is only a part of a great therapeutical scheme. The essential thing is to take such a large view of the physiological and pathological processes as

will give the right indications to call upon each and all of the therapeutical agents at our command. To fix the mind too intently upon any one of these agents is to incur the danger of neglecting others, and of losing sight of the principle which ought to guide the application of all, as one force directed to one end."

A NEW ANTIDOTE FOR MORPHINE.—In the *Internationale Klinische Rundschau* for January 27, 1889, PROFESSOR ARPAD BOKAI recommends picrotoxine as an antidote for morphine, on the ground that it exerts an antagonistic action to morphine on the respiratory centres; for, while morphine tends to paralyze these centres, picrotoxine exerts a powerful stimulating effect. Since, therefore, death in morphine poisoning is usually attributable to paralysis of the respiratory centre, on this ground alone picrotoxine should be indicated as a valuable antidote. Further, morphine may produce such rapid reduction in blood-pressure as to endanger life; while picrotoxine, on the other hand, is a powerful stimulant to the vaso-motor centre, and is in this respect also an antagonistic to morphine. Professor Bokai adds that the action of morphine on the cerebrum is directly exposed to that exerted by picrotoxine. Finally, Professor Bokai suggests that the previous administration of a small dose of picrotoxine might reduce the danger of asphyxia in chloroform narcosis.—*Therapeutic Gazette*, March 15, 1889.

AN EARLY SIGN OF ENDOCARDITIS.—DR. DUCLOS, of Tours, writing in the *Revue Générale de Clinique et de Thérapeutique*, January 17, 1889, records a fact of his experience, in regard to commencing endocarditis, which may possibly be of value as an aid in the early recognition of this affection. While in charge of a military hospital he chanced to have a large number of young soldiers suffering from acute articular rheumatism under his care. One day, while listening to the heart-sounds of one of these patients, his finger being at the same time on the radial pulse, he was struck with the want of synchronism between the ventricular contraction and the pulsation at the wrist, the latter being delayed about two-thirds of a second. The following day a systolic apex murmur was heard. Thinking that this retardation of the radial pulse might have some significance in connection with the subsequent development of endocarditis, he took pains to note its occurrence in other cases, and found that it was followed by a murmur at the end of from twenty-four to thirty-six hours in every instance. These observations were extended over a period several years, and were confirmed in a number of cases by Professors Parrot and Potain.

The author has no conclusive theory to offer in

¹ American Journal of Obstetrics, 1882.

explanation of this phenomenon, but he thinks that it is probably due to a weakening of the muscular fibres subjacent to the endocardium. He compares it to the weakened respiratory murmur frequently observed at the beginning of a pleurisy a few hours before a friction sound is developed or effusion takes place. It would be interesting to learn whether this want of synchronism is present in the beginning of endocarditis arising in the course of other diseases, but the author has few observations bearing on this point to record. He has noted it, however, in two cases of typhoid fever and in three of erysipelas, in which endocarditis, subsequently developed.

Dr. Duclos draws some practical conclusions, in regard to treatment, based upon the early recognition of the affection, and he believes that he has succeeded in arresting the disease, in certain cases, before irreparable injury had resulted. His plan is to apply immediately a large flying blister over the præcordial region, or, in default of this, a mustard-plaster, dry cups, or leeches. He increases also the dose of the remedy that is being at the same time given for the rheumatism. Of course, a strict enforcement of recumbency is also indicated.

When we consider the importance of an early diagnosis of endocarditis, and the possibility of arresting the disease if detected in its incipency, this alleged premonitory symptom of the affection is worth testing in order to determine the amount of practical utility that it may possess.—*Medical Record*, March 30, 1889.

WHEN TO PRESCRIBE DIGITALIS.—Notwithstanding the increasing additions to the list of so-called cardiac medicaments digitalis still holds its position as the most certain and most widely used; but in order to derive all the good possible from it is necessary to understand clearly the indications, and not to give it indiscriminately, as is too often done. MR. HUCHARD has set forth these indications very clearly in his recent work, "When and How Should Digitalis be Prescribed."

In order to understand clearly the indications and counter-indications, the valvular affections of the heart must be divided into four stages or periods. The first is the period of *ensystole*. During this time the lesion is compensated, and nothing should be done in the way of medication; all our efforts are to be confined to maintaining good hygiene. Digitalis is useless.

During the second period, that of *hypersystole*, the contractions are violent, and compensation is exaggerated. Hygiene still plays an important part, and the cardiac sedatives, aconite, arsenic and the bromides, are indicated; digitalis is injurious.

The situation is entirely different in the period of *hyposystole*, or temporary asystole. The cardiac muscle and vessel become asthenic. This is the

stage of cedemas, congestion of the viscera, dropsies; the heart beats softly and feebly, etc. Digitalis is now of the greatest service; it is here triumphant.

Finally, in the period of *asystole* or *amyocardia* the cardiac muscle is profoundly degenerated; there is paresis of the heart, the *definitive cardioplegia* of Gubler. Digitalis is still sometimes useful, but it may in time become inefficacious, and occasionally it is injurious. Caffein in large doses is here sometimes very valuable.

Huchard considers a maceration of the drug as the best form for administering it. He does not give the infusion, which is preferred by some physicians, for, when it is necessary to act quickly, we cannot wait for twelve hours, which time is required for macerating. This is the method for making the maceration:

R. Leaves of digitalis, in powder . . . 25 to 40 cent.
Cold water 300 grams.

Macerate for twelve hours, and filter carefully, in order to avoid the retention of a certain amount of the powdered digitalis, which is capable of producing nausea and vomiting by its irritant action upon the mucous membrane of the stomach. The infusion may be sweetened with any agreeable syrup.

This maceration should be taken in five or six doses during the day, between meals; the digitalis should be prescribed in diminishing doses; thus, 40 centigrams the first day, 30 cgr. the second, 20 cgr. the third, etc. As a rule, the digitalis should be suspended after four or five day's use. (*Journal de Médecine et Chirurgie Practiques*.)—*New Orleans Medical and Surgical Journal*, March, 1889.

MAGISTERIUM BISMUTHI IN INFANTILE SUMMER DIARRHŒA.—In the St. Petersburg weekly *Russkaia Meditzina*, No. 30, 1888, DR. A. PÜGINOFF says that subnitrate of bismuth constitutes the most reliable remedy for epidemic summer diarrhœa in nurslings. He gives the drug in large doses, feeling sure that a pure preparation is excreted *per anum* wholly and in an unaltered state. Thus, to an infant of 4½ months, he administers 1½ or 2 grains every 2 hours. The main advantages of the subnitrate over all other means are stated to be these: 1. The drug does not give rise to any untoward accessory symptoms. 2. It is readily taken and perfectly well borne. 3. It acts on the intestinal tract both as a sedative and as an antiseptic.

THE TREATMENT OF CORNS.—DR. C. McDERMOTT writes to the *British Medical Journal* that a saturated solution of salicylic acid in flexible collodion is an excellent remedy for corns. The corns should be painted twice a day. It takes about twelve days for their complete removal.

CLIMATIC INFLUENCE IN PHTHISIS.

The reception of a neat reprint edition of the excellent paper on the "Preferable Climate for Phthisis," read at the Ninth International Medical Congress, Washington, 1887, by DR. CHAS. DENISON, Denver, reminds us that there are few questions of more practical importance to the general practitioner, than the one so frequently asked by his patient affected with pulmonary phthisis, *i.e.*, Will a change of climate benefit me and if so, where shall I go? In assuming to answer the anxious inquirer by simply saying, "You better go to the mountains, or to California, Colorado, Texas or Florida, or in more general terms, to a mild, dry, and elevated region," more patients have been sent astray than in any other department of medical practice. That a large proportion of cases of chronic diseases of the lungs, including tubercular phthisis can be arrested, and many of them permanently cured by residence in a proper climate, commenced at the proper stage of the disease, has been proved by ample experience. The possession of accurate knowledge concerning the elements that give special character to climate and their influence on the functions of the human body, and the ability to ascertain the extent and stage of progress of the morbid conditions in each patient are the essential qualifications needed by every practitioner, who would do justice to those who depend upon him for advice. The studies necessary to gain the knowledge mentioned as constituting the first part of these

qualifications do not hold as prominent a position in the curriculums of study, either preliminary or medical, devised for those who would enter the ranks of the medical profession as they should. Therefore Dr. Denison well says in the beginning of his paper: "Hitherto, the chief obstacles in the way of right conclusions have been: 1. Ignorance of the exact nature and progress of the disease, and 2. A lack of appreciation of the relative importance of different climatic attributes in its arrest."

A thorough knowledge of physics, topography and geology should constitute an essential part of the qualifications needed for entering upon the study of medicine; and the application of the facts and physical laws furnished by these branches, in the study of physiology, pathology, and etiology, in the medical course, should be much more systematic and thorough than has hitherto been done in most of our medical colleges. The word *climate* is used to indicate the sum or aggregate of qualities possessed by the atmosphere in any given locality and at any specified season of the year. The chief elements that determine the quality of a climate are 1. purity of the air or freedom from foreign ingredients; 2. temperature; 3. dryness; 4. rarefaction as determined by altitude; 5. the amount of sunshine; 6. electricity; 7. variability as opposed to uniformity; and 8. motion or wind. All these climatic elements are influenced directly or indirectly by the topography or configuration of the earth's surface, the composition of the soil and superficial strata in each locality, and the presence or absence of large bodies of water. The two elements, purity and rarefaction bear a direct ratio to altitude, while the temperature, dryness and amount of sunshine and electricity are influenced much by the altitude, latitude and composition and configuration of the earth's surface. An uneven, hilly or mountainous surface composed largely of sand, gravel or rocks, not only admits of free drainage, retaining less water for evaporation, but it both absorbs and radiates heat with rapidity; while a level surface composed of a liberal intermixture of clay, with the latitude and altitude the same, retains the water for evaporation, thereby giving to the superimposed atmosphere a much higher degree of moisture, while the absorption and radiation of heat are much slower. As the amount of sunshine and electricity depend

largely upon the amount of atmospheric moisture and currents with variability of temperature, it is readily seen that the composition and configuration of any locality must be taken into consideration in estimating the special characteristics of its climate. For the same latitudes we may deduce the following climatic law: The purity, coolness, dryness, rarefaction and sunshine will be in direct proportion to the altitude, and the unevenness and porosity of the surface; while the electricity and direction and velocity of the winds will be modified by the proximity of mountain ranges or large bodies of water. The influence of the several climatic elements mentioned in this law on the functions of respiration, circulation, elimination and nutrition, and their bearing or adaptability to the treatment of different stages of pulmonary phthisis will be briefly considered in the next issue of THE JOURNAL. In the meantime we wish every practitioner would read the paper of Dr. Denison, and as much of similar literature by other authors as he can find.

INTUBATION IN DIPHTHERITIC LARYNGITIS.

In the *New York Medical Journal*, March 9, 1889, DR. DILLON BROWN gives the result of 200 cases of intubation of the larynx for diphtheritic croup, performed by himself, and in addition collates from the published statements of 165 other operators in America, Germany, France, England, Spain and Canada, an aggregate of 2,168 cases, making, with his own, a total of 2,368 cases, by 166 operators. Of the whole number 647, or 27.3 per cent., recovered. Of the 200 cases operated on by Dr. Brown 54, or 27.3 per cent., recovered. He mentions having seen 23 additional cases that recovered without operation, and 4 that died, in which intubation was urged but refused. The alleged causes of death in 144 of the fatal cases intubated by Dr. Brown were: extension of the disease to the bronchi, 63; sepsis, 24; pneumonia, 15; exhaustion, 11; nephritis and convulsions, 11; sudden heart failure, 8; extension and pneumonia, 7; asphyxia 2; tuberculosis, 1; general paralysis, 1; and scarlet fever and sepsis, 1.

The general table of 2,368 cases given by Dr. Brown includes 158 cases reported by Dr. F. E. Waxham, of Chicago, with 43 recoveries. In a clinical lecture by Dr. Waxham, published in the

North American Practitioner, March, 1889, he gives 30 additional cases, with 17 recoveries, making the total number of his cases 188, with 60 recoveries, or 31.3 per cent. Both Drs. Brown and Waxham report a higher ratio of recoveries in their later than in their earlier operations. This is attributed to the acquisition of greater skill by practice in the insertion and removal of the tube, and in guarding against accidents and complications. May not an important part of the higher ratio of recoveries be the result of an earlier resort to intubation without waiting until the patient is in such imminent danger of suffocation or fatal exhaustion, as is usual before obtaining permission to perform tracheotomy? And yet up to the present time the tabulated statements of both intubation and tracheotomy differ but little in the relative ratio of recoveries and deaths; and we have no means of knowing how many of those subjected to these operations would have recovered if no operation had been performed. The impression made upon the popular mind is, that every case recovering after either operation is a life saved by the operative procedure that would have been otherwise certainly lost. Such a conclusion, however, is not justified by a fair consideration of all the facts. To ascertain the real value of either intubation or tracheotomy in true diphtheritic croup we must be able to compare the results of the treatment of an adequate number of cases, in the same season, of similar age and in similar sanitary surroundings without operative procedures, with those subjected to the most skillful operative methods.

As stated above, Dr. Brown mentions having seen 27 cases that were treated without either intubation or tracheotomy, of which 23 recovered and 4 died. Another writer mentions 13 cases that were so bad operative procedures were deemed useless, and yet 4 of them recovered without such aid. Both Drs. Brown and Waxham concede the marked benefit derived from the efficient use of the bichloride of mercury as an internal remedy. The former states that of the last 115 cases on which he had practiced intubation 50 had been treated medicinally without the bichloride and 12, or 24 per cent., recovered. The other 65 were treated with the bichloride in doses of gr. $\frac{1}{40}$ to gr. $\frac{1}{80}$ every hour, and 24, or 36.9 per cent., recovered. In the foregoing comments we do not desire to discourage the judicious resort to operative

procedures in diphtheritic laryngitis when suffocation is imminent from the direct obstruction of the larynx, but simply to suggest caution in resorting to surgical methods too indiscriminately, and to the neglect of the most efficient medical treatment in the early stages of the disease.

THE OFFICIAL PRELIMINARY PROGRAMME.

We publish to-day the programme of the general sessions of the coming meeting of the Association. A better selection of those to deliver general addresses could not have been made. The reports from the officers of Sections also promise a most interesting and instructive series of papers for them. Excellent arrangements have been made for the meetings of the Sections. The social part of the meeting has not been forgotten. One of the pleasantest features planned by the Committee of Arrangements will be a steamboat excursion on the fourth day of the sessions, given by the Rhode Island Medical Society, to Providence, when the Rhode Island Hospital and Butler Hospital for the Insane will be inspected, and an old-fashioned clambake will be enjoyed at a shore resort on the way back to Newport.

EDITORIAL NOTES.

TEXAS STATE MEDICAL ASSOCIATION.—The next annual meeting of this Association will be held in San Antonio, commencing April 23, 1889.

THE OFFICIAL NOTICE OF THE NEXT ANNUAL MEETING of the American Medical Association, by the Permanent Secretary, will be found in the columns for Association News in the present number.

PHILADELPHIA POLYCLINIC.—The following recent additions and changes have been made: A chair of Diseases of the Mind and Nervous System and a chair of Obstetrics and Diseases of Children have been established; Professor S. Weir Mitchell has been appointed to the first and Edward P. Davis to the second. Dr. B. Alex. Randall has been appointed to the chair of Diseases of the Ear, in place of Dr. Burnett, resigned.

CHICAGO MEDICAL COLLEGE CHANGES.—At a recent meeting of the Trustees and Faculty, the regular annual college term was extended to seven months. Dr. G. W. Webster, who had given the course on Physiology during the past year, was

unanimously elected to the professorship; and an *optional* full four years' course was recommended and will appear in the annual announcement.

THE WOMAN'S HOSPITAL MEDICAL COLLEGE OF CHICAGO held its nineteenth annual Commencement on the 2d inst., at which the degree of Doctor in Medicine was conferred upon 25 young women. The Rush Medical College had graduated 127; the College of Physicians and Surgeons 48; and the Chicago Medical College 46, young men; making the total number of graduates from the four regular medical colleges of Chicago for 1889, 246.

ARMY MEDICAL BOARD—VACANCIES IN THE MEDICAL CORPS.—In the columns for miscellaneous notices and news items of the present number, will be found an official notice from the Surgeon-General of the U. S. Army, stating that an Army Medical Board will be in session in New York City from May 1 to 31, 1889, for examination of candidates for appointment in the Medical Corps of the United States Army, to fill existing vacancies. We are informed that there are seven vacancies existing at present in the Medical Corps, to which another will be added in July by the retirement of a medical officer, making eight appointments to be recommended by the Board. Among the many recent graduates of the medical schools and hospitals of our country, there must be some ambitious for military life with its duties and honors, and if so, they cannot have a more favorable opportunity for presenting themselves than the one indicated in the Surgeon-General's notice alluded to above.

THE ETIOLOGY OF CONSTITUTIONAL IRREGULARITIES OF THE TEETH has been very carefully studied in some recent papers by DR. EUGENE S. TALBOT, of Chicago, the papers having been recently published in pamphlet form. He shows that constitutional irregularities of the teeth prevail to a greater extent among the idiotic, deaf and dumb, and blind, than among an equal number of strong and healthy persons, and claims that arrest of development is the result of malnutrition during embryonal and infantile growth, influenced by consanguineous marriages, scrofula, drunkenness in parents, prenatal influences, intra-uterine education, and constitutional diseases, or of inflammation of the osteophytic membranes *in utero*. Irregularities of the teeth, he says, do

not exist among normal or large jaws, while among those who have abnormally small jaws, the majority have irregular teeth. In a second paper Dr. Talbot makes some very strong arguments in favor of arrest of development of the maxillary bones being due to race crossing, climate, and soil. It is shown that these irregularities of the teeth and jaws are not found in pure races nor in aborigines, while they are common in mixed races, and more common in the offspring of races differing widely from each other. Conditions of life, climate, soil, and food, play an important part in these irregularities, when taken in connection with race-mixture. Dr. Talbot then goes on to consider the subject in detail, and his papers are well worth careful study.

HYDRONEPHROSIS RELIEVED BY POSITION.—MR. R. H. A. HUNTER reports in the *British Medical Journal*, the case of a woman with a painful swelling in the right side, which had been increasing in size for three weeks. This was diagnosticated as a case of hydronephrosis, and the patient was directed to rest in bed with the pelvis elevated up on pillows. After remaining in this position for a few hours the patient suddenly felt a desire to pass water, and passed about a pint. In a short time she again passed about a pint and a half, and the swelling had disappeared.

ASSOCIATION NEWS.

American Medical Association. Fortieth Annual Meeting.

To be held in Newport, R. I., June 25, 26, 27 and 28, 1889.

The Fortieth Annual Session will be held in Newport, R. I., on Tuesday, Wednesday, Thursday and Friday, June 25, 26, 27 and 28, commencing on Tuesday, at 11 A.M.

"The delegates shall receive their appointment from permanently organized State Medical Societies, and such County and District Medical Societies as are recognized by representation in their respective State Societies, and from the Medical Department of the Army and Navy, and the Marine-Hospital Service of the United States.

"Each State, County and District Medical Society entitled to representation shall have the privilege of sending to the Association one delegate for every ten of its regular resident members,

and one for every additional fraction of more than half that number: *Provided*, however, that the number of delegates for any particular State, territory, county, city or town shall not exceed the ratio of one in ten of the resident physicians who may have signed the Code of Ethics of the Association."

Members by Application.—Members by Application shall consist of such members of the State, County and District Medical Societies entitled to representation in this Association, as shall make application in writing to the Treasurer, and accompany said application with a certificate of good standing, signed by the President and Secretary of the Society of which they are members, and the amount of the annual membership fee, five dollars. They shall have their names upon the roll, and have all the rights and privileges accorded to *permanent members*, and shall retain their membership upon the same terms.

The following resolution was adopted at the last session: That in future, each delegate or permanent member shall, when he registers, also record the name of the Section, if any, that he will attend, and in which he will cast his vote for Section officers.

Secretaries of Medical Societies, as above designated, are earnestly requested to forward, *at once*, lists of their delegates.

Also, that the Permanent Secretary may be enabled to erase from the rolls the names of those who have forfeited their membership, the Secretaries *are, by special resolution*, requested to send to him, annually, a corrected list of the membership of their respective Societies.

AMENDMENTS TO THE CONSTITUTION.

Amendment proposed by Dr. N. S. Davis, of Illinois:

"The General Committee shall be composed of two members from each State and Territorial Medical Society entitled to representation by delegates in the Association, and from the Medical Departments of the U. S. Army, Navy, and Marine-Hospital Service. They shall be chosen by the members registered and present at each annual meeting from each State and Territory, and from the Medical Corps of the U. S. Army, Navy and Marine-Hospital Service, acting separately, on the third day of each annual meeting; each delegation reporting the names of the members chosen to the Permanent Secretary of the Association on the same day, that they may be announced by him at the opening of the morning session of the fourth day. At the first election each delegation shall choose two members of the General Committee, one of whom shall serve one year, and the other two years, and at each annual election thereafter one member shall be chosen to serve for two years, thus making the term of office of members of the General Committee two years. It shall be

the duty of the General Committee thus constituted, to organize by choosing annually a Chairman and Secretary, and such subcommittees as may be found necessary to facilitate the work that may be assigned to it; to meet annually at the place and on the day preceding each annual meeting of the Association, and as often during that week as may be necessary; to nominate, on the third day of each annual meeting, all the general officers of the Association (none of whom shall be members of its own body), the members of the Committee of Arrangements, the Committee on Necrology, seven members of the Judicial Council, and three members of the Board of Trustees for Publication, for election by the Association; to recommend the place and time of holding the next annual meeting; and to consider and report upon all subjects that may be referred to it by vote of the Association. The presence of one-third of the whole number of members elected to the General Committee shall constitute a quorum for the transaction of business. If, at any annual meeting of the Association, it shall be found at the close of the general meeting of the first day that a quorum of the General Committee is not present, it shall be the duty of the President and Permanent Secretary to fill the vacancies in the Committee temporarily by selections from the lists of delegates registered as present from the States to which the vacancies belong."

Should this provision be adopted by the Association, the Permanent Secretary should be authorized to substitute the name "General Committee" for "Nominating Committee," wherever the latter occurs in other parts of the Constitution and By-Laws.

Amendment offered by Dr. J. M. Keller, of Arkansas:

"To change the By-Law whereby the officers of the Sections are elected by the Sections."

Amendment offered by Dr. N. S. Davis:

"Strike out the last clause of paragraph VII, relating to individually affixing names to the Constitution and Regulations of this Association."

Amendments offered by Dr. H. N. Moyer, of Illinois:

"There shall be created a Section of Pharmacy and Materia Medica, which shall have its own autonomy, in like manner as the Section in Dental and Oral Surgery. Reputable members of the State Pharmaceutical Associations shall be eligible as members of the same on presentation of credentials from their State Secretary, but shall have no voice in the general sessions of the Association.

"The Section of Surgery shall hereafter be denominated the Section of Surgery and Gynecology.

"There shall be created a Section of Anatomy and Physiology.

"The Section of Obstetrics and Diseases of Women shall be abolished.

"The Section of Diseases of Children shall hereafter be denominated the Section of Obstetrics and Pædiatrics.

"The Section of Dermatology and Syphilography shall hereafter be denominated the Section of Dermatology and Genito-urinary Diseases.

"The Section of Medical Jurisprudence shall hereafter be denominated the Section of Mental and Nervous Diseases.

"The Section of State Medicine shall hereafter be denominated the Section of State Medicine and Medical Jurisprudence.

"The Section of Practice of Medicine, Materia Medica and Physiology shall hereafter be denominated the Section of Internal Medicine."

Committee of Arrangements: H. R. STORER, Chairman, Newport, R. I.

WM. B. ATKINSON, M.D., Per. Sec'y.

SECTIONS.

"The Chairman of each Section shall prepare an address on the recent advancements in the branches belonging to his Section, including such suggestions in regard to improvements in methods of work, and present, on the first day of its annual meeting, the same to the Section over which he presides. The reading of such address not to occupy over forty minutes. . . ."—*By-Laws*.

Practice of Medicine, Materia Medica and Physiology.—Dr. F. C. Shattuck, Chairman, Boston, Mass.; Dr. G. A. Fackler, Sec'y, Cincinnati, O.

Obstetrics and Diseases of Women.—Dr. W. H. Wathen, Chairman, Louisville, Ky.; Dr. A. B. Carpenter, Sec'y, Cleveland, O.

Surgery and Anatomy.—Dr. N. P. Dandridge, Chairman, Cincinnati, O.; Dr. W. O. Roberts, Secretary, Louisville, Ky.

State Medicine.—Dr. J. Berrien Lindsley, Chairman, Nashville, Tenn.; Dr. S. T. Armstrong, Sec'y, U. S. M.-Hosp. Service.

Ophthalmology.—Dr. George E. Frothingham, Chairman, Ann Arbor, Mich.; Dr. G. C. Savage, Sec'y, Nashville, Tenn.

Laryngology and Otolaryngology.—Dr. W. H. Daly, Chairman, Pittsburgh, Pa.; Dr. E. Fletcher Ingalls, Sec'y, Chicago, Ill.

Diseases of Children.—Dr. J. A. Larrabee, Chairman, Louisville, Ky.; Dr. C. J. Jennings, Sec'y, Detroit, Mich.

Oral and Dental Surgery.—Dr. F. H. Rehwinke, Chairman, Chillicothe, O.; Dr. E. S. Talbot, Sec'y, Chicago, Ill.

Medical Jurisprudence.—Dr. James G. Kiernan, Chairman, Dunning, Ill.; Dr. T. B. Evans, Sec'y, Baltimore, Md.

Dermatology and Syphilography.—Dr. L. D. Bulkley, Chairman, New York; Dr. W. T. Corlett, Sec'y, Cleveland, O.

A member desiring to read a paper before a Section should forward the paper, or its title and

length (not to exceed twenty minutes in reading), to the Chairman of the appropriate Section at least one month before the meeting.—*By-Laws*.

OFFICIAL PRELIMINARY PROGRAMME.

FIRST DAY, TUESDAY, JUNE 25.

Assemble in Music Hall, Bellevue Avenue, at 11 A.M.

Meeting called to order by Dr. Horatio R. Storer, Chairman Committee of Arrangements.

Prayer. Rev. Thatcher Thayer, D.D. (Cong.), the senior clergyman of Newport.

Reading names of delegates and others thus far registered, by Permanent Secretary, Dr. Wm. B. Atkinson, of Philadelphia.

Announcement of the programme for the day, of halls for the Sections, that papers not already listed be handed to Chairman of Committee of Arrangements for reference to appropriate Sections, that Judicial Council meet at 2 P.M. at Newport Casino, and that, to prevent the usual haste and confusion, the delegates from the different States hold their separate meetings, to elect members of the Nominating Committee, at 9:30 A.M. Wednesday, at the Music Hall, half an hour before the general session.

Addresses of Welcome by Hon. Thomas Coggeshall, Mayor of Newport; by Dr. Henry E. Turner, of Newport, President of State Board of Health, on behalf of the profession of Newport; and Hon. James H. Eldredge, M.D., of East Greenwich, ex-President of Rhode Island Medical Society, on behalf of the profession of Rhode Island.

Presidential Address, Dr. W. W. Dawson, of Cincinnati, Professor of Surgery in the Medical College of Ohio.

SECOND DAY, WEDNESDAY, JUNE 26.

Meeting called to order by the President of the Association, at 10 A.M.

Prayer.

Reading continuation of registry list, of programmes for the day, and call for reports as to elections upon Nominating Committee.

Address on Medicine, by Dr. Wm. Pepper, of Philadelphia, Provost of the University of Pennsylvania.

Report of the Trustees of THE JOURNAL.

Consideration of proposed Amendments to the Constitution.

Announcement of Nominating Committee, and that it will report at close of Thursday's general session.

THIRD DAY, THURSDAY, JUNE 27.

Meeting called to order by the President, at 10 A.M.

Prayer.

Reading of continuation of registry list, and of

programmes for the day, and notice that all new business must be introduced at to-day's session.

Address on Surgery, by Dr. Phineas S. Conner, of Cincinnati.

Introduction of New Business.

Report of Treasurer.

Report of Librarian.

Report of Rush Monument Committee.

Report of Nominating Committee.

FOURTH DAY, FRIDAY, JUNE 28.

Meeting called to order by the President at 9 A.M.

Prayer.

Reading of continuation of registry list, and of programmes for the day.

Address on State Medicine, by Dr. W. H. Welsh, of Baltimore.

Report of Necrologist.

Reading names of newly elected officers of the Sections and Delegates to Foreign Societies.

Introduction of the in-coming by the retiring President.

Response by the former.

Final Adjournment.

Special Attention is called to the following Rules of the Association :

It shall be the duty of every member of the Association who proposes to present a paper or report to any one of the Sections, to forward either the paper, or a *title* indicative of its contents, and its *length*, to the Chairman of the Committee of Arrangements at least one month before the annual meeting at which the paper or report is to be read. It shall also be the duty of the Chairman and Secretary of each Section to communicate the same information to the Chairman of the Committee of Arrangements concerning such papers and reports as may come into their possession or knowledge for their respective Sections, the same length of time before the annual meeting. And the Committee of Arrangements shall determine the order of reading or presentation of all such papers, and announce the same in the form of a programme for the use of all members attending the annual meeting. Such programme shall also contain the rules specified in the By-laws and Ordinances concerning the consideration and disposal of all papers in the Sections.

No report or other paper shall be entitled to publication in the volume for the year in which it shall be presented to the Association, unless it be placed in the hands of the Committee of Publication on or before the first day of July. It must also be so prepared as to require no material alteration or addition at the hands of its author.

Every paper or address received by this Asso-

ciation, or by a Section, and ordered to be published, and all reports of Committees, and all plates or other means of illustration, shall be considered the exclusive property of the Association, and shall be published and sold for the exclusive benefit of the Association.

ORDINANCES.

Resolved, That the several Sections of this Association be requested, in the future, to refer no papers or reports to the Committee of Publication, except such as can be fairly classed under one of the three following heads, namely: 1. Such as may contain and establish *positively* new facts, modes of practice, or principles of real value. 2. Such as may contain the results of well-devised original experimental researches. 3. Such as present so complete a review of the facts on any particular subject as to enable the writer to deduce therefrom legitimate conclusions of importance.

Resolved, That the several Sections be requested, in the future, to refer all such papers as may be presented to them for examination by this Association, that contain matter of more or less value, and yet cannot be fairly ranked under either of the heads mentioned in the foregoing resolution, back to their authors with the recommendation that they be published in such regular medical periodicals as said authors may select, with the privilege of placing at the head of such papers, "Read to the Section of the American Medical Association on the day of 18 ." (Vide *Transactions*, vol. xvi, p. 40.)

Resolved, That no report or other paper shall be presented to this Association unless it be so prepared that it can be put at once into the hands of the Permanent Secretary, to be transmitted to the Committee of Publication. (Vide *Transactions*, vol xvii, p. 27.)

SOCIETY PROCEEDINGS.

Medical Society of the District of Columbia.

Stated Meeting, December 12, 1888.

THE PRESIDENT, THOMAS C. SMITH, M.D., IN THE CHAIR.

DR. A. A. HOEHLING read the history of a case of

PHTHISIS PNEUMONICA ET LARYNGITIS CHRONICA.

(See page 481.)

DR. BERMANN said he was much interested because in later years other ways of treating laryngeal phthisis have been tried with success—Rosenthal used beech-wood, creasote—published in Berlin four or five months ago—with doses be-

ginning with 1 decigramme; second week 2 decigrammes, continued for a week, increasing 1 decigramme daily each week, until he reached 8 decigrammes daily. He, Dr. Bermann, had treated a severe case with creasote with marked benefit. Another treatment of laryngeal phthisis is by lactic acid applications, which he has used and been well satisfied.

DR. HOEHLING said in the case reported they had only made the man comfortable, and had not attempted any specific treatment.

DR. MURRAY said the disease is most distressing when it invades the larynx. He has never found anything to heal tubercular laryngeal ulcer in his own experience—has never tried lactic acid, insufflations of iodoform of idol, morphia, and of iodol and morphia, with good results. He thought the treatment with creasote was suggested about ten years ago by a Frenchman, and not by the Germans as he understood Dr. Bermann to claim.

DR. BERMANN did not claim that Rosenthal originated creasote treatment.

DR. MCARDLE: Having observed the effect carboic acid has upon the kidneys wondered if creasote would have any deleterious effect upon kidneys if used as Dr. Bermann had described.

DR. BERMANN: The beech-wood creasote did not seem to act as other species did, and he had noticed no bad effect.

DR. C. E. HAGNER did not believe from his own experience that any tuberculous ulceration of the larynx was curable, and did not believe these ulcers ever existed without sufficient evidence of tuberculosis elsewhere. Thought from present state of knowledge we might as well give up when we saw the bacilli. Had never seen a tubercular laryngeal ulcer cured.

DR. H. L. E. JOHNSON did not think the creasote obtained from beech-wood could act physiologically different from any other variety; there was no difference chemically.

DR. BERMANN: Creasote from beech-wood had a different specific gravity; he did not know the chemical difference.

The discussion on Dr. Schaeffer's paper on

MICROSCOPICAL DIAGNOSIS OF CANCER

was resumed. (See pages 403 and 424.)

DR. BERMANN did not think it impossible to diagnose cancer of kidney and bladder from cells in the urine; he wished to put himself on record thus. Thought the case ought to be discussed otherwise than as cancer on account of the changes in the pathological condition due to the long presence of the stone in this case.

DR. GRAY was under the impression the diagnosis was encephaloid carcinoma, and the specimen slide which he showed proved to be a squamous epithelioma.

DR. SCHAEFFER said as to the statement of

encephaloid carcinoma he had merely taken the report; he had not seen the specimen at all.

DR. GRAY did not agree with Dr. Bermann. The majority of authorities on the subject deny the existence of a specific and diagnostic cell of cancer, in fact those claiming the existence of such a cell are in a noticeable minority, he could only recall to mind one such, namely, Ziegler, and his statements even not very positive. He did not believe it possible to diagnose cancer of kidney positively, unless fragments of the tumor were found in the urine, then it was possible by seeing the relation of the cells, the mere presence of a multinuclear epithelial cell is not diagnostic of cancer, because such cells may be formed in any inflammation of the urinary tract. A multinuclear epithelial cell simply means that the cell is undergoing division, and represents some form of karyokinesis. Diagnosis of cancer by such cells is simply guess-work. Considered the epithelial cell of cancer as a normal cell in an abnormal place.

DR. BUSEY: Could fragments of sufficient size come through the ureters?

DR. GRAY thought it were possible.

DR. J. F. THOMPSON was obliged to Dr. Gray for the opinion he had expressed. He had spoken the other evening in a general way and from a surgical standpoint. His remarks were meant to apply to cells found floating in the urine, and he had consulted his books and still believes there is no distinctive cancer cell. Dr. Gray had expressed his views so well that he had nothing else to say. He quoted from Holmes' Surgery in support of his argument.

DR. BERMANN differed from the opinions of Drs. Gray and Thompson.

DR. THOMPSON: The stone in the kidney in this case would change the appearance of the epithelial cells to such an extent that it would be utterly impossible to distinguish a cancer cell in it.

DR. SCHAEFFER, in closing, thought the subject had been exhausted, and was much gratified at the amount of discussion his paper had elicited. He had quoted extracts from a work on surgery to show that the attitude of modern surgeons was somewhat against the microscopist. There was such a thing as cancer and that it contained cells. When Dr. Gray said *he*, Dr. G., could not distinguish cancer cells except there be considerable tissue *he*, Dr. S., would not contradict him, because a gentleman who made such beautiful sections as did Dr. Gray was excusable for not having devoted a sufficient amount of time to the other branch of the microscopist. Dr. Thompson stands with the attitude of the majority of modern surgeons, but it was this theory *he*, Dr. S., was combatting.

DR. T. E. MCARDLE read the history of the diagnosis, course and treatment of a case of

PERITYPHLITIS.

(See page 406.)

DR. THOMPSON detected deep-seated fluctuation in this case at his first visit and operated on the following morning, making an incision $2\frac{1}{2}$ inches in length, and carefully dissecting down to the peritoneum, and after incising it the pus was discharged, introduced two fingers and examined the appendix, carefully washed out the wound with an antiseptic fluid and left a drainage tube in the wound for a day.

DR. THOMAS E. MCARDLE reported a case of ANEURISM OF THE AORTA, WITH SPECIMEN.

W. A. B., was born in Warren, Ohio, Dec. 15, 1845. He entered the army as drummer boy of Co. C, 84th Regiment Ohio Volunteers, not being old enough to enlist otherwise. In 1863 he entered the volunteer navy as Master's mate in the Mississippi squadron, and was soon promoted to an ensigncy. At the close of the war he was honorably discharged. He suffered with pleurisy during his infantry service at Cumberland, Md., and from malarial fever while on the Tennessee river. On April 19, 1887, he had an attack of "catarrhal strangulation," (?) from which he nearly died. The following August he began to complain of a pain in his chest, and his side and back ached. He was sent to Cleveland to consult the family physician, who diagnosed functional heart trouble and great nervous prostration. He recommended change of scene in a warmer climate, and in November the patient left for Florida, where he remained until driven away by the yellow fever in July, 1888. He seemed much benefited by his residence in Florida, gained flesh and almost completely lost his cough. In the spring, however, he suffered from fever and ague, and quickly lost all he had gained. He came to Washington in July, 1888, but I did not see him until Nov. 18. At that time he was in a very feeble condition. He suffered from a distressing cough, had severe pain in upper part of right side, had no appetite, and slept badly. He would not remain in bed, however, but persisted in getting up and dressing himself. Three days later I saw him again and he seemed not to suffer so acutely. On the morning of Nov. 30, whilst getting out of bed to dress himself, he suddenly expired.

Necroscopy by Dr. D. S. Lamb: Slight deformed prominence of upper, anterior, inner portion of right side of thorax corresponding to sternum and first three ribs. Upper right side of sternum eroded from pressure of aneurism. Right lung compressed by aneurism and by an effusion of blood in pleura which had clotted; firmly adherent to sac. There were also several old pleuritic bands of lower lobe not connected with aneurism; also three firm nodules, size of peas, in margin of lower lobe, two of them darkly pigmented, the other with a calcareous centre. Left

lung cedematous, serum in upper lobe colorless, in lower lobe stained with blood. Heart normal, displaced somewhat downwards by pressure of sac; contained small dark clots. Aorta atheromatous. On right side of ascending portion of arch was an opening 1.5 inch in diameter, leading into an aneurismal pouch, $6 \times 4 \times 4$ inches in size, rather spherical in shape, with thin walls, well lined with laminated clot, and closely adherent to upper lobe of right lung and sternum as stated. Extreme right portion of sac had ruptured into right pleura, which contained more than $\frac{1}{2}$ gallon of recent blood clot. Abdominal viscera, especially the liver, depressed well downwards towards pelvis by sac and coagula in pleura; all of them bloodless, otherwise normal. Bladder empty, normal.

Philadelphia County Medical Society.

Stated Meeting, January 23, 1889.

THE PRESIDENT, W. W. KEEN, M.D., IN THE CHAIR.

DR. EUGENE P. BERNARDY read a paper on BINIODIDE OF MERCURY. ITS ANTISEPTIC USE.

When I read my second paper "On the Value of Biniodide of Mercury as an Antiseptic in Obstetrics," before the Philadelphia Obstetrical Society (April 1, 1886), I fully intended leaving the results of my investigations to the medical profession, and let them, by further trial, confirm the correctness of my conclusions.

In reading several papers on antiseptics, the biniodide of mercury is declared insoluble, and therefore difficult to use; in one paper, the cost is the objection, it being stated to be more costly than the mercuric chloride. It is to be sincerely hoped that pecuniary considerations will never interfere in the use of any medicine that will assist in saving a human life. I certainly made myself clear in regard to making the biniodide a soluble salt, and called attention to the addition of *iodide of potassium*.

Dr. P. K. Bolshesolsky,¹ of St. Petersburg, (*Vratch*, 1887, Nos. 10 and 11, page 220), from numerous experiments made by himself in Professor A. P. Dobroslavin's laboratory, concludes that biniodide of mercury is a more powerful and less poisonous antiseptic than corrosive sublimate. A solution of 1 to 4,000 destroys putrefaction-microbes more completely than a corrosive sublimate solution of 1 to 2,000. The biniodide dissolved in a solution of potassium iodide was recently tried, with apparently good results, in three cases of laparotomy, under Professor A. I. Krassowski; for washing the floor a solution of 1 to 4,000 was employed; for disinfecting the

hands, 1 to 2,000; for instruments, from 1 to 2,000 to 1 to 3,000.

In the *Gazette de Gynécologie*, January 1, 1888, Professor Krassowski,² of St. Petersburg, reports a series of eleven laparotomies in which he used as an antiseptic equal parts of biniodide of mercury and potassium iodide in solution. Two deaths occurred from causes not connected with the operation; in each case post-mortem examination showed union of the wound by first intention, and absence of septic inflammation. The mercurial was first used in a strength of 1 to 1,000, which was progressively diminished to 1 to 4,000.

Krassowski concludes that a solution of 1 to 4,000 is an efficient antiseptic, and that this substance is less irritant than the bichloride, and can be applied to the integument in a 5 per cent. solution without producing irritation.

At the recent annual meeting of the Italian Obstetrical and Gynecological Society, Prof. Mangiagalli³ stated that the biniodide of mercury was a more active antiseptic than corrosive sublimate, less dangerous, and less injurious to instruments. The strength of the solution was 1 to 4,000, iodide of potassium, chloride of potassium, or chloride of sodium being used to increase the solubility of the biniodide.

Dr. Rogée-Saint Jean d'Angely (*Semaine Médicale*) states that the biniodide of mercury is not irritant to wounds, and is a more powerful antiseptic than carbolic acid. It has no odor, and an alcoholic solution of 1 to 300 is soluble in all proportions in warm water. Lister's dressing is expensive, and not adapted for use in armies. Since 1885, he has employed exclusively the biniodide with dressings of cotton and gauze, and in 108 operations (32 major) had only one death.

Mr. David Webster,⁴ in the *International Journal of Surgery*, October, 1888, states that the use of bichloride of mercury solutions in ophthalmic surgery has been abandoned at the Manhattan Eye and Ear Hospital, on account of corneal opacities following a certain number of cataract operations wherein those solutions were employed. The surgeon of the Royal Ophthalmic Hospital, about the same time, reported a similar experience. In March last he gave up the bichloride in surgical cases having corneal relations, and now uses Panas' fluid in all iridectomies and cataract extractions. The formula for this fluid is: biniodide of mercury, 1 part; absolute alcohol, 400 parts; pure water, 20,000 parts. The results under this plan have been unusually satisfactory.

In the number of the *Medical News* of June 16, 1888, is a copy of an article from the *Lancet* of

May 12, 1888, on "A New Antiseptic Soap," which states that, until quite recently a satisfactory soap containing as an antiseptic one of the salts of mercury, has been difficult to prepare on account of the alkaline soap refusing to yield a good lather, oleate of mercury being formed—a compound which has little or no germicidal action. One of the most powerful antiseptics of the mercury salts is, as is well known, the bichloride. Moreover, it is cheap, and easily soluble, but it has the disadvantage of being extremely poisonous, and easily reduced by albuminoid matter with which it combines, thus being rendered inactive. In a paper recently read before the Society of Chemical Industry, in Glasgow, by John Thomson, the solubility of the red biniodide of mercury (which is claimed to be even a more powerful antiseptic than the bichloride) in iodide of potassium has been made use of. It is stated to be permanent, having no tendency to separate, and to be more germicidal in its properties than any other antiseptic soap yet known. Experiments were made to demonstrate this. Sterilized silk threads were suspended in a solution of the biniodide soap for ten minutes, after being saturated with solutions containing well-known microorganisms, amongst which were the streptococcus scarlatinae (Klein), bacillus subtilis, orange sarcina, white bacillus from Tweed water, organisms from putrid urine, the micrococcus of osteo-myelitis, aspergillus nigrescens, spores from various fungi, yellow micrococcus from pus, putrefactive organisms, bacterium termo, and bacillus scarlatinae (Edington). The threads were then carefully washed to remove the soap, and placed in sterilized gelatine in the ordinary way. The threads were controlled by first sterilizing and then plunging into nutrient gelatine; if no growth occurred, they were accepted as being fit for use in the experiment. Washing the threads previously contaminated with organisms, two or three times carefully with distilled water, was shown, by experiment, not to remove the organisms; for, on being placed in the gelatine, growth readily took place. The results, as shown in tables, are very remarkable. In all the experiments, with a few very uncertain exceptions, growth of the organisms was completely prevented, even after the lapse of four days. Similar experiments, made with "carbolate of mercury" soap, showed it to be less powerful as a disinfectant, and much slower in its germicidal action. In experiments carried out in the same manner with antiseptic and ordinary soaps, it was shown that the growth of the organisms, in many cases, was not prevented. The importance of such a soap in medical and sanitary science is very obvious. The biniodide soap has been used in the treatment of eczema with well marked success, especially where the irritation is due to the fermentations

of accumulated secretions, the fermentations being set up by microorganisms. It has also met with similar success when used in parasitic skin diseases, such as favus and ring-worm. As a parasiticide, too, the importance of its application to patients during the period of desquamation in scarlet fever is evident.

The interesting experiments, and the careful manner in which they were carried out, are my excuse for giving the above notes in full. They more than corroborate my opinion of the value of biniodide of mercury as an antiseptic.

As will be seen by the title of my present paper, I have embraced a larger scope than in my two previous papers, which were entirely of obstetrical cases. I have divided my paper: First, history of obstetrical cases; second, history of abdominal abscess intercurrent with typhoid fever; third, surgical cases; fourth, application of the biniodide of mercury wool to the chest in pulmonary troubles; fifth, as a disinfectant in the discharges (alvine) of typhoid fever.

(To be concluded.)

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

Meeting of the New York County Medical Association—A Paper on Diphtheria by Dr. J. Lewis Smith—Its Etiology—Mode of Propagation—The Specific Cause received chiefly by Inhalation with the Air—Capability of being Communicated from Man to Animals and the Reverse—Means of Prevention by different Modes of Disinfection, etc.

At the last meeting of the New York County Medical Association Dr. J. Lewis Smith read a paper on *The Cause, Mode of Propagation, and Prevention of Diphtheria*. Stating that, although the belief that this disease is of microbic origin is constantly being strengthened by the investigations made in regard to it, it is still a matter of doubt what microbe (or possibly microbes), is the causal agent, he first gave an admirable résumé of the bacteriology of the subject, as developed by various observers during the last twenty years. It was, he said, the conclusions of Drs. Curtis and Satterthwaite, based on their investigations made in 1877 under the auspices of the New York Board of Health, on the etiology and pathology of diphtheria, that evidently prepared the way for the theory that the bacteria themselves are not the direct cause of the disease, but that ptomaines produced by their agency may be. In his most recent utterances Oertel expressed the opinion that, while bacterial organisms gave rise to diphtheria, they did so not by their direct action, but by producing a ptomaine which infects the system

and causes the disease to become constitutional. The microbe itself was mostly confined to the surface, where the action of the virus is widespread and deep. The most eminent pathologists of the present time, said Dr. Smith, do not express any more positive opinions in reference to the action of the specific principle or germ of diphtheria. In the earliest formed membranes Oertel found that many kinds of microbes could be isolated, but practically there are two chief kinds: chain-forming cocci (the streptococcus), and rod-shaped bacteria with rounded extremities (bacilli). In a pseudo-membrane of twelve hours' continuance micrococci abounded mostly on the surface, but in the fibrinous network the bacilli, often in colonies, preponderated. In a specimen of twenty-four hours' duration the upper surface was full of cocci, and below them were bacilli. In concluding this portion of the subject Dr. Smith stated that during the past year Dr. T. Mitchell Prudden, one of the most skilled and trustworthy of our pathologists, has been making a series of careful investigations, the results of which will shortly be published in the *American Journal of the Medical Sciences*, which seem to indicate the strong probability that the specific microbe of diphtheria is a streptococcus.

In treating of its mode of propagation, he said that no fact was better established than that diphtheria does not arise *de novo*. Like eruptive fevers, it is produced by the reception in or upon some part of the system of the preëxisting specific poison. The extreme contagiousness of diphtheria from person to person is well known, and the virus adheres tenaciously to objects on which it happens to alight. The clothing of a patient, even when the disease is of the mildest form, his bedding, the furniture of his room, and the objects which he handles, may for weeks afterward communicate the disease. Dr. Sternberg, in his recent Lomb Prize Essay, also mentions the fact that all damp, foul places, such as sewers, cellars and ill-ventilated spaces under floors, afford conditions favorable for the development and propagation of the diphtheritic virus. The virus, once received, may be propagated in such a place for an indefinite time and, ascending in the vapors which arise from this culture-bed, it is liable to communicate the disease to any one who inhales it. Thus, in New York City, prior to 1850, although foul sewers and unsanitary conditions existed, there was no diphtheria; but in the decade following 1850 this disease was introduced. The germ made its way into the sewers under ground, and now wherever sewer-gas escapes into the domiciles of the city it carries with it the diphtheritic poison. The amazing vitality and power of propagation of this virus are apparent when we reflect that it has permanently infected the New York sewers; so that children in all parts of the city are constantly falling ill with the disease. It is

chiefly by exposure to the emanations from this widely extending culture-bed and to walking cases, often so mild that there is little or no complaint of the throat or impairment of the general health, that diphtheria is so prevalent here. The diphtheritic virus is so subtle, and its vitality and power of propagation so great, that when it is once established in a sewered city the disease can probably never be stamped out, as cholera and yellow fever can.

Diphtheria is commonly communicated by the inhalation of air containing its specific principle, from whatever source the latter may be derived. More rarely the contagion is contracted by means of direct contact with some infected substance, such as a particle of the diphtheritic exudate, mucopurulent secretion from an infected surface, or the blood of a patient. Observations are also accumulating which show that diphtheria, or a disease closely resembling it, occurs among animals, and is sometimes communicated from them to man. Having mentioned several recorded instances of this, he spoke of experiments by different observers which would seem to show that diphtheria can be transmitted from man to animals, and stated that if this were true, it might be inferred that it could likewise be transmitted from animals to man. Such observations and experiments, he went on to say, render it probable that genuine diphtheria, equally fatal, and attended by the same symptoms and anatomical characters as in man, does occur in birds, whether wild or domesticated, and in certain quadrupeds, as the rabbit. Nevertheless, it should be added that certain eminent pathologists, among them Virchow, have doubted the identity of animal and human diphtheria. With our present light upon the subject, he thought it was evident that, since our relations to domestic animals are so close, if they are sick with any disease resembling diphtheria the same precautionary measures should be taken to prevent infection of the family as in human diphtheria. Having stated that milk was a culture medium of various microbes, and that it was probable that it may be the medium of communication of diphtheria, as well as of scarlet fever, Dr. Smith referred to several instances of such apparent communication observed by different writers.

In concluding this portion of the subject he said that the fact that diphtheritic virus may be conveyed long distances without losing its power is now admitted from the many observations that have been made, and the statistics given by Prof. C. W. Earle, of Chicago, in his paper on this subject before the Ninth International Medical Congress, render it probable that the infection is not infrequently transmitted over long distances to salubrious rural localities by means of articles of clothing and merchandise.

In speaking of the prevention of diphtheria he

said that, as regards the small extent of the area of its contagiousness and the persistence and highly infective character of its virus within that area, this disease resembles scarlet fever, and is unlike measles and pertussis, the specific principles of which, although they have a wider contagious area, are more volatile and more quickly dissipated. The most efficient method of preventing the propagation of diphtheria, he went on to say, is the isolation and disinfection of patients, the prompt and thorough disinfection of the apartments occupied by them, with their furniture and bedding, and the exclusion or prevention of all noxious germs. He thought there was reason to believe that disinfection, as commonly practiced, is inadequate, and in this connection he referred to the outbreak of diphtheria in the spring of 1888, which he described in full in the paper on "Diphtheria of the New-born," which he read in May last before the Fifth District Branch of the New York State Medical Association. Here, it will be remembered, the ward was carefully fumigated with the dry vapor of burning sulphur, and after the fumigations there were found in the apartment quantities of living bacteria which were identical with those found in connection with diphtheritic cases previously treated there.

As bearing on this result he read an interesting communication from Dr. E. R. Squibb, the eminent chemist, of Brooklyn, sent in compliance with a request for his opinion; in which the latter stated that in our present state of knowledge all that could be said in regard to sulphur fumigation against infectious material was that it is of doubtful efficacy, with the weight of the highest authorities in bacteriology against it. But to this it must be added that it is still largely used by very intelligent bodies in large institutions, health-boards, etc., where it would not be likely to long maintain an unearned confidence. Dr. Squibb believed that many of the recent failures with sulphur fumigation might perhaps be due to the fact that the fumes were applied dry, while formerly the surfaces of the apartment to be disinfected were all wetted and the pot of burning sulphur was set in water or wet sand, in order that the heat might evaporate off a constant supply of watery vapor. Most, if not all, chemical disinfectants were in a state of tension, ready to change on coming in contact with the matter to which they were applied, and these changes were either by oxidation or di-oxidation; while the moment of greatest power or activity was the moment of change, when, by reacting on infectious matter they passed from a state of tension to a state of rest under new relations. The agency through which these changes almost invariably became operative was the vapor of water. Having explained the chemical reactions which took place when sulphur was burned in a moist atmosphere said that if no moisture was supplied that present in the air

and on the surfaces of the chamber would soon be used up, and the dry gas remain in a comparatively inactive, inefficient condition. The anhydride would necessarily destroy all organisms which breathed in any degree, because breathing surfaces were moist. But in embryonic life protected by shell if the shell were dry the gas would be impotent. Many bacteriologists had admitted that burning sulphur would kill bacteria, but not germs.

Having mentioned that Dr. Llewellyn Eliot had recommended during the continuance of a case of diphtheria the constant evaporation of turpentine over a water bath for the purpose of destroying the virus of the disease, Dr. Smith said that he had himself employed the following prescription for disinfection during his attendance on cases with apparently such good results that he felt encouraged to continue its use:

R

Acid. carbolic	
Ol. eucalypti aa	f 5j
Spts. terebinth.	f 5j

℞

Of this, two tablespoonfuls are added to one quart of water, and the mixture placed in a shallow pan. It is to be maintained in a constant state of simmering in the room occupied by the patient.

He next prescribed the disinfection carried out some years ago by Prof. R. Ogden Doremus in the wards of Bellevue Hospital, where pyæmia had been prevalent, by means of chlorine gas, freshly set free; and then went on to say that diphtheria would continue to spread and largely increase the aggregate of deaths unless stringent measures were employed to prevent its propagation by mild walking cases. He saw no way of doing this except by enforced inspection and surveillance of children by parents, nurses and teachers; and he thought that wherever diphtheria was at all prevalent children who had the least sore throat should be excluded from the schools and compelled to remain at home.

In order to adopt adequate preventive measures the fact should also be recognized that third persons who have had no diphtheritic symptoms themselves and infected apparel or furniture may be the medium of communication. After recurring to several recorded instances of this kind, he said that nurses and physicians attending diphtheritic patients should avoid as far as possible the infection of their persons and clothing. Physicians in examining the fauces of children with diphtheria were very liable to receive upon their faces or clothes particles of the pseudo-membrane or infected muco-pus ejected by the violent cough excited by the examination. This might to a considerable extent be avoided by standing one side during the examination, but he himself constantly carried corrosive sublimate with him;

washing his face and hair with a solution of it before leaving the apartment if he suspected that he had received any particle of the infectious material upon his person. Physicians thus exposed should also make use of precautionary measures before going to visit other children.

In conclusion, he referred to the paper read by Dr. H. Caillé, before the New York Academy of Medicine, in January, 1888, on the prevention of diphtheria, in which he stated that occasionally children had a recurrence of diphtheria each spring or autumn. Thinking that such children might perhaps harbor or carry with them the germ of the disease, he selected eight children having a permanent residence who had had repeated attacks of diphtheria, and subjected them to prophylactic treatment. All carious teeth were extracted or filled, and the mouth was rinsed after each meal with a solution of potassium chlorate, sodium chlorate, or sodium borate. The solution was also gargled or drawn through the nostrils. With this treatment the children had escaped the customary diphtheritic attacks during the two years that had elapsed since it was undertaken.

LETTER FROM BOSTON.

(FROM OUR OWN CORRESPONDENT.)

Twentieth Anniversary of the Dental School of Harvard University.

At Huntington Hall, on March 11, were held exercises commemorating the twentieth anniversary of the Harvard Dental School. A large audience, composed of the alumni and their friends, many of whom were ladies, was present, and was much interested in the literary exercises. Chas. W. Elliot, LL.D., the President of Harvard University, presided in his usual easy and attractive manner, and in his brief words of welcome said that they had come together to felicitate the school and themselves on the work which the school had accomplished in the past twenty years. The school had some trials at its birth. The real difference of opinion was as to whether a dentist should be first educated in medicine and then adopt dentistry as a specialty, or whether a special school should be established for the sole education of dentists. Within the twenty years of the life of this school, there has been a wonderful change in medical education. When this school was founded, a medical student was required to pass four months of the winter three times, in attending precisely the same course of medical lectures. Now a medical student is required to pass three years or four, in the study of medicine, and it is true that the dental student of to-day passes as much time in medical study on his way to the dental degree, as the medical student did twenty years ago on his way to the medical degree. I

believe that the Dental Department of Harvard University was the first one to be established in connection with a university of the liberal arts and the learned profession. This example has been followed by other universities, as, for example, the Universities of Pennsylvania, Michigan, Iowa and California. There is here a recognition of the worth and dignity of the calling which, twenty years ago, was lacking. We have also to rejoice together that the dental department of Harvard University has sent into the community a goodly number of highly trained and skillful men. Its instructions have been widely diffused not only over this country, but over Europe as well. The Dental School has more foreign students than all the other departments of the University put together, and these men have returned to their native countries, carrying with them the education of the Harvard Dental School. We believe that we have done good far beyond the limits of our own country.

In his address on the "*Twentieth Anniversary and History of the Dental School*," L. D. Shepard, D.M.D., who was for many years connected with the school, first as Adjunct Professor and then as Professor in the department of Operative Dentistry, said: Twenty years ago but one school, our own, had any connection with a classical University. Now eighteen claim a more or less intimate connection with universities, and five with medical colleges, leaving seven, the same number as twenty years ago, distinctively dental colleges. To-day no college is considered respectable, or its diplomas recognized by the Examining Boards of the States, which graduates a man, no matter how many years of practice he may claim, except after actual attendance upon two courses of lectures in separate years. In important advances, our institution has generally been a leader and always has warmly seconded any advance proposed by another school.

In narrating the history of the origin of the School Dr. Shepard said that the annual address of the Massachusetts Dental Society, in 1865, was delivered by its President, the late Dr. Nathan Cooley Keep, and in accordance with his suggestions, a committee from the Society conferred with a committee from the Medical Faculty. The corporation of Harvard College, after full investigation of the reports, voted, on July 17, 1867, to establish the Dental School, and that the Faculty consist of the Professors of Anatomy, Physiology, Chemistry, and Surgery, in the Medical School; and of three new Professors, of Dental Pathology and Therapeutics, Operative Dentistry, and Mechanical Dentistry. In this vote the Board of Overseers afterwards concurred.

The spirit of that first Faculty was shown at the very commencement, for it decided that the Dental School of Harvard University should rank right and justice above expediency, should re-

quire only that a student should be a man of good moral character, and know no distinction of nativity or color, and among the six who twenty years ago received the dental doctorate, Robert Tanner Freeman was the peer of any as a student and a gentleman. His name stands to-day upon our records and will remain in history as the first of his race to receive dental collegiate honors.

At a Faculty meeting on Feb. 16, 1869, it was "Voted that *Dentariæ Medicinæ Doctor* [D.M.D.] be recommended to the Board of Government of Harvard University as the title for the degree to be conferred upon the graduates of the dental department." And on Feb. 27, 1869, the Corporation established this degree. There was no thought of arrogating to ourselves any special superiority or claim of exclusiveness. Further it was expected that the new degree would approve itself to other universities, which might have dental departments, and thus gradually become the accepted degree. That such has not been the result is no fault of ours. On March 6, 1869, was held at the old Medical College the examination of candidates for the degree. On March 10th occurred the Commencement. Professor Edward H. Clark, M.D., delivered the Address, and Professor Henry J. Bigelow, M.D., conferred the degrees upon the six successful candidates. We have met to-day to celebrate the quiet and modest exercises which took place twenty years ago in that old historic building.

In the Fall of 1871, upon the recommendation of the Faculty, the Corporation voted to abolish the custom, which was universal with the dental colleges, of allowing a practice of five years to be equivalent to the first course of study and the graduation of students after attending one course at the school. This was the most important innovation ever made in its good influence upon the profession and the colleges. It was equally important in its disastrous effect, pecuniarily considered, upon the School. The Faculty considered that this custom had been a great hindrance to progress. The Harvard School was the first, and for many years the only one, to enunciate the truth, and at great expense to itself that the college was designed to educate the young incomers to the profession, and not simply to supply the doctorate to the more or less skilled handiworkers who had practiced without a degree for five or more years. Boldly living up to its convictions it maintained unassisted for years this higher standard, and thus cut itself off from the support of a very large class of practitioners throughout New England who, having no degree and wishing one, would otherwise have attended its instruction and have been enrolled among its alumni.

In the winter of 1872 written examinations were substituted for oral, and the candidate was required to pass successfully in each subject instead of a majority of them, as had been the cus-

tom. The Harvard School was the first to recognize that the ordinary terms of study and discipline were too short to prepare the student properly for practice, and a summer course of four months immediately following the winter session was established. The summer school was a success and the idea was soon imitated by nearly all of the schools of the country.

On March 1, 1875, an entire change in the curriculum was made and the new scheme embraced

1. A consolidation of the winter session and the hitherto optional summer session into one school year extending from the last of September to the first of June.

2. A progressive course of instruction, extending over two years, the teaching of one year not being repeated in the next.

3. An examination at the end of the first year in anatomy, including dissection, physiology and general chemistry. Unless the student successfully passed two of these he could not be admitted to the studies of the second year.

4. At the end of the second year an examination in dental pathology, dental materia medica and therapeutics, oral surgery, and surgical pathology, operative and mechanical dentistry.

5. All the examinations to be conducted in writing.

6. The candidates must have passed a satisfactory examination in all of the above mentioned subjects.

This scheme has been in operation ever since, but few slight modifications from time to time having been considered necessary. It has resulted in securing fine scholarships and excellent skill. The entrance examination was not originated by the Harvard Dental School, and it was adopted by us, not from a feeling of its need, but because it seemed a good rule for all dental colleges. Harvard has never been selected by the ignorant any more than by the indolent. The Faculty have preferred to maintain this higher course rather than lower the standard to secure more students. The true principle was aptly expressed by President Eliot in one of his annual reports: "The University should be more concerned to have a very good school than a very large one." There are now sixty of its graduates occupying prominent positions in Boston alone. This School and that of the University of Michigan, founded in 1875 upon the same plan, received, without solicitation or knowledge beforehand, a distinguished mark of approbation from the General Medical Council of Great Britain. Of all the American Dental Colleges, their diplomas only exempt the holders from examination for registration and license to practice in Great Britain.

At the conclusion of the Address, Rev. Alexander McKenzie, D.D., who for fourteen years has been Secretary of the Board of Overseers of Harvard College, was introduced to speak on the

"*Relation of the University to the Professional Schools.*" He said that the schools are essentially part of the university which sends its blood and life through the world and shares its name and honor. It is a governmental relationship; for the schools are under the charter and statutes and authorities of the university. It is therefore a nourishing relation, the university is to care for the schools. The method of the bestowal must depend on what theologians call "distributive justice," which provides that every one connected with the system be treated according to his deserts and in relation to the great ends of the system, but it must see that no department gets anything that does not belong to it. The university has the strongest desire to advance the dental school, but its treasury has not the money which can be given to the school. The dental school must have money of its own. The record of the school is most creditable and its influence is felt throughout the world. It has forty-two students and eleven professors, and a fund of only \$2,150, being dependent on the fees received from students for running expenses.

"*The Needs of the Dental School*" were set forth by Thomas H. Chandler, D.M.D., Dean of the School for the past fourteen years, who said: We may say briefly that the School lacks everything except zealous and competent instructors and devoted alumni. In our efforts to accomplish the work we have undertaken, we have been hampered and pinched on every side for twenty years. This work is the improvement of dental education by raising its standard, and the consequent elevation of the profession of Dentistry. A dental school should have a building specially adapted to its purposes, with large and well lighted operating-rooms and laboratories fitted with every necessary appliance, pleasant and comfortable lecture-rooms, clean and light reception-rooms for the patients who throng to it for treatment, suitable dressing-rooms, and whatever else can be devised for the comfort and convenience of its instructors, students and patients, not forgetting a well stored professional library and a good cabinet.

The Harvard Dental School, through the charity of the Medical School, has the use of a part of the old Medical building on North Grove Street. The operating-room is a large square room, well lighted near the windows, but unsuited near the middle for the delicate manipulations of tooth filling. This room is also used for a lecture room. The laboratory is in the basement, low, poorly lighted and inconvenient. We need a good building. We never shall be able to build one for ourselves; for our only resources are the fees received from the students, and if the amount of these fees exceeds in any year the running expenses, the surplus goes toward paying off our debt to the University treasury, a debt which exceeds by several thousand dollars all our assets.

Secondly, we need a fund for salaries, in order that the School may have a reasonably permanent corps of instructors in operative and mechanical dentistry, and may not lose year after year its trained teachers just when experience has made them doubly valuable. Professors and instructors should be paid. It is only in quite recent years that salaries have been paid to any teachers, except the demonstrators, who gave to the School the whole of their working time. Even now, the highest salary paid to a Professor is \$500 a year, while a lecturer is paid only \$100, and a clinical instructor only \$50 a year. As soon as an instructor's time becomes decidedly valuable for private practice, a struggle begins between his love of teaching and his interest in the School on the one hand, and his sense of obligation to make the most profitable use of his time on the other. The result of this struggle generally is that after a few years the School loses an experienced instructor. The remedy for this evil is, of course, larger salaries.

Thirdly, the Infirmary needs a fund for its support. It is a charity which relieves much excruciating pain and prevents more. The community does not expect physicians and surgeons to maintain at their own expense hospitals for the sick and wounded. On the contrary, it gives great endowments and levies taxes to support such hospitals. It should also support a dental hospital.

The literary exercises were followed by a banquet at which were Governor Ames, with many officers of the University, members of the Dental and Medical Faculties and their friends, numbering considerably over a hundred. x.

Pregnancy, with Accidental Hæmorrhage: Difficult to Control and Difficult in the Diagnosis.

Dear Sir:—The following case seems to me to be of special interest:

Mrs. P., æt. 30 years, mother of five children and had had three miscarriages. Her mother died of disease of some one of the abdominal organs. Mrs. P. had her last monthly period the latter part of last July. On September 24, whilst sitting in a carriage watching a procession passing by, she was taken suddenly with uterine hæmorrhage and was carried into a drug store in a fainting condition. On November 20 she had recurrence of the hæmorrhage, and also on December 21. I saw her first on November 20. On December 29 she had another hæmorrhage. At this time she took to her bed and remained there. The hæmorrhage never afterwards totally ceased. January 1, 1889, patient had profuse hæmorrhage; also January 16 and 21. On the morning of January 23 I tamponed in order to stop hæmorrhage. From this time on to February 14 there was con-

stant oozing of blood. The patient became very weak and exsanguinated. The uterus was of abnormal size and very hard in the left hypogastric region; especially was this so the last month of her pregnancy. The os was that of a pregnant woman, but it was high up and difficult to reach with the index finger. If this be a case of pregnancy, where does the hæmorrhage come from? Is it a case of placenta prævia? If not a case of pregnancy, is it a case of fibroid tumor? Is it hydatids? or is it epithelioma? I could not hear the foetal heart, neither could I, from palpation, make out pregnancy. I was in doubt till the pains came on at 6 A.M. February 14, and ceased at 2 P.M., dilating the os as large as a silver dollar, when I was first enabled to make a positive diagnosis of pregnancy. On February 16, at 1 A.M., the pains recommenced, and at 4.20 A.M. the liq. amnii sac enveloping a five to six mo. *in utero* child was born, which presented an egg-like appearance. The membranes contained no liquid and were tough and difficult to tear to expose the fœtus. The child was dead. The placenta was on the heel of this egg-like tumor, and showed unmistakable evidence of previously for some time having been about one-third part separated from the walls of the uterus. The treatment consisted of small and repeated doses of ergot; except when profuse hæmorrhage occurred large doses of this drug were given.

The child measured $13\frac{1}{2}$ inches; that is, 7 inches from the crown of the head to the umbilicus, and $6\frac{1}{2}$ inches from the umbilicus to the soles of the feet. Mrs. P. has now fully recovered.

JOHN M. BATTEN, M.D.

BOOK REVIEWS.

RECTAL AND ANAL SURGERY; with Description of the Secret Methods of the Itinerant Specialists. By EDMUND ANDREWS, M.D., LL.D., Professor of Clinical Surgery in the Chicago Medical College and the Mercy Hospital, etc., and EDWARD WYLLYS ANDREWS, A.M., M.D., Professor of Clinical Surgery in Chicago Medical College and the Mercy Hospital. Second Edition Revised and Enlarged, with Illustrations and Formulary. Chicago: W. T. Keener. 1889.

It is but a short time since we noticed in these columns the peculiar merits of the first edition of this work. The fact that a second edition has been called for so soon is proof that its merits have been appreciated by the profession. The present edition is published in good style and the additions to the text are valuable; making it one of the best practical monographs on the subjects of which it treats, with which we are acquainted.

MISCELLANY.

MEDICAL GRADUATES.—Following are the numbers of graduates of medical colleges that have recently closed their sessions: Bellevue Hospital Medical College, 138; Long Island College Hospital, 47; University of Kansas City, 15; Medical Department of Arkansas Industrial University, 17; Kansas City Medical College, 18; Woman's Medical College of Pennsylvania, 36; University of Kansas City, Medical Department, 15; Miami Medical College, 22 (not 12 as stated); Chicago Medical College, 45; Toledo Medical College, 8; University of the City of New York, 180.

NUT-SHELL IN THE TRACHEA.—A piece of nut-shell, a third of an inch long and nearly that at its widest part, with one very sharp point, was coughed up by a 4-year old patient of Dr. H. Swift, of Adelaide, Australia, after being in the trachea fifty-two days. Tracheotomy had been done and the child had scarlet fever in the meantime, but made a good recovery. The case is reported in the *Australasian Medical Gazette* for December. The chief point of interest is stated by Dr. Swift to be the length of time the foreign body was retained without giving rise to any serious complication such as deep ulceration, abscess, collapse of lung or pneumonia.

THE NATIONAL ASSOCIATION OF RAILWAY SURGEONS will hold its annual meeting at St. Louis, Mo., on Thursday and Friday, May the 2d and 3d, 1889. The prospects are that this will be one among the largest gatherings of medical men ever assembled in this country. Dr. W. B. Outten, of St. Louis, is the Chairman of the Committee of Arrangements, and everything will be complete for the accommodation of the surgeons. Any information desired can be had by addressing the Secretary, C. B. Stemen, M.D., Fort Wayne, Ind.

THE *Memphis Journal of Medical Sciences* is a new monthly journal, edited by Drs. Alexander Erskine, B. G. Henning, T. J. Crofford, S. A. Rogers, W. B. Rogers, and James L. Minor.

At the Centennial Celebration of Georgetown University Washington, D. C., last month, the degree of LL.D. was conferred upon Dr. John B. Hamilton, Surgeon-General Marine-Hospital Service.

AUSTRALIAN RABBITS.—The Commission appointed to report on the means for arresting the multiplication of rabbits in Australia has reported that the experiments made under the direction of Pasteur, with the virus of chicken cholera, are an entire failure.

BEQUEST TO DENVER MEDICAL COLLEGE.—Mr. Jacob Haish, of DeKalb, Illinois, has recently given \$15,000 to the medical department of the University of Denver, which makes a total of \$40,000 that Mr. Haish has given to the University.

HEALTH IN MICHIGAN, MARCH, 1889.—For the month of March, 1889, compared with the preceding month the reports indicate that influenza and pleuritis increased and that scarlet fever decreased in prevalence.

Compared with the preceding month the temperature in the month of March, 1889, was much higher, the absolute humidity was more, the relative humidity and the night ozone were less, and the day ozone was the same.

Compared with the average in the month of March, in the three years, 1886-88, measles, intermittent fever, tonsillitis, inflammation of bowels, consumption of lungs and rheumatism were less prevalent in March, 1889.

For the month of March, 1889, compared with the average of corresponding months in the three years 1886-'88, the temperature was considerably higher, the absolute

humidity was slightly more, the relative humidity was less and the day and the night ozone were slightly more.

Including reports by regular observers and others, diphtheria was reported present in Michigan in the month of March, 1889, at 29 places, scarlet fever at 32 places, typhoid fever at 8 places, measles at 12 places, and small-pox at 5 places.

Reports from all sources show diphtheria reported at 2 places less, scarlet fever at 20 places less, typhoid fever at 3 places less, measles at 5 places more, and small-pox at 5 places less in the month of March, 1889, than in the preceding month.

CLAIRVOYANT "PHYSICIANS."—The opinion of the Supreme Court of Wisconsin, by Lyon, J., holding that a clairvoyant physician is liable for failure to exercise the ordinary skill and knowledge of a physician in good standing, practicing in the vicinity, and not merely to the ordinary skill and knowledge of clairvoyants. If he holds himself out as a medical expert and accepts employment as a healer of diseases, but relies for diagnosis and remedies upon some occult influence exerted upon him, or some mental intuition received by him when in an abnormal condition, he takes the risk of the quality of accuracy of such influence or intuition. There are so many persons now who assume to act as physicians and take the lives of people in their hands that this decision holding them to a strict liability may perhaps be timely.—*Legal News*.

AN ARMY MEDICAL BOARD will be in session in New York City, N. Y., from May 1 to 31, 1889, for the examination of candidates for appointment in the Medical Corps of the United States Army, to fill existing vacancies.

Persons desiring to present themselves for examination by the Board will make application for the necessary invitation to the Secretary of War, before May 1, 1889, stating the place of birth, place and State of permanent residence, and enclosing certificates based on personal knowledge from at least two persons of repute, as to American citizenship, character and moral habits. Testimonials as to professional standing, from professors of the medical college from which the applicant graduated, and of service in hospital from the authorities thereof, are also desirable. The candidate must be between 21 and 28 years of age, and a graduate from a *Regular Medical College*, evidence of which, his Diploma, must be submitted to the Board.

Further information regarding the examinations and their nature may be obtained by addressing the Surgeon-General, U. S. Army, Washington, D. C.

JNO. MOORE, Surgeon-General U. S. Army,
Surgeon-General's Office, Washington, D. C., April 1, 1889.

THE DISTRICT MEDICAL SOCIETY OF CENTRAL ILLINOIS will hold its annual meeting in Pana, April 30, 1889. Reports on Surgery, Obstetrics and Practice of Medicine will be read, and several papers on important subjects are promised. President, Jacob Huber, M.D., Pana; and Secretary, J. H. Miller, M.D., Oconee, Ill.

VACCINATION.—That obtuse fraction of the community which prides itself upon blind opposition to vaccination might be moved to a more liberal attitude on the subject if it would condescend to look into the results that have been reached under its practical application. In Paris, for instance, where the law requiring vaccination is feebly enforced, the mortality from small-pox ranges from 136 to 10.1 to the 100,000 inhabitants, while in the principal German cities, where the vaccination laws are rigidly enforced, the death-rate is but 1.44 to the 100,000 inhabitants. London, under compulsory vaccination, has a death-rate from small-pox of but 0.6 to the 100,000 inhabitants. On the other hand, in the Canton of Zurich, in Switzerland, since the compulsory vaccination law

was repealed in 1883, the death-rate from small-pox has risen steadily from 8 to 85 to the 100,000 inhabitants.—*American Analyst*.

NECROLOGICAL.—Dr. A. M. Orcutt, of Hardwick, Mass., died February 11, 1889, aged 65 years. He graduated from the College of Physicians and Surgeons, Columbia College, New York, in 1849, commenced the practice of medicine soon after in Hardwick, and in October, 1850, married Mary, the daughter of Theophilus Knight, who still survives him with three daughters. Dr. Orcutt possessed superior native ability and a thorough knowledge of his profession, and enjoyed an extensive medical practice for nearly forty years. He had the confidence and esteem of all classes of the community and equally of his professional brethren. He was honored with various local offices, and served as Representative in the Legislature of the State in 1874. He became a member of the American Medical Association in 1884.

LEPROSY IN INDIA.—Under a call from the home Government, made in view of the possibility of more efficient measures by the State for the prevention and treatment of leprosy in India, the local authorities have furnished returns from which is gleaned the following information: In 1881, according to the census of that year, there were in India 131,618 lepers, of whom 98,982 were men and boys, and 32,636, not quite one-third, were women and girls. It is doubtful, however, if these figures represent the whole number, as many of these miserable creatures are secreted by friends. Of this great army of lepers about nine-tenths prefer local charity to organized relief, and resent even the slight restraints to which they are subjected in institutions devoted to their treatment, and avoid them in every possible way. As the disease can be stamped out only by the complete segregation of sexes and the life confinement of all tainted with it (measures so repugnant to the Hindoos as to be considered entirely impracticable), about all the Government can do for these poor wretches is to grant medical assistance and relief in voluntary hospitals and asylums, knowing that any relief can prove only temporary, and that even that cannot always be given.—*New York Evangelist*.

A WOMAN in Edinburgh, Scotland, is pregnant at the age of 62, it being her twenty-third time. She was also pregnant at the ages of 47, 49, 51, 53, 56 and 60. The case is attracting much attention from the physicians of that place, as it is a rare one.—*Wes. Med. Rep.*

ALUM IN BREAD.—Professor J. W. Mallet, of the University of Virginia, has been pursuing an interesting course of investigations into the effects produced by the use of alum in bread, and has found that, as has long been assumed, it is injurious. In the United States the greater part of the baking powders sold, it has been found, are made with alum, the acid phosphate of calcium, bicarbonate of soda and starch. The result of Professor Mallet's inquiry, as given in the *Pharmaceutical Journal*, has been to show that these powders give off very varying proportions of carbonic acid gas, and therefore different proportions have to be used for the same quantity of flour to produce the requisite porosity in bread. When moistened with water they yield small quantities of aluminum and calcium salts in a soluble form. Most of them leave, after use, the greater part of their alumina in the form of phosphate; but when acid phosphate of calcium is not used alumina is left. As the baking temperature in the interior of bread does not exceed 212° F., neither the water of combination of alumina or of its phosphate is removed from the residues of baking powder so used. However, in doses not very greatly exceeding such quantities as may be derived from bread as commonly used, Professor Mallet has found that hydrate and phosphate of alumina produced an inhibitory effect upon gastric digestion. He considers that this effect is probably a consequence of the union of albumina with

the acid of the gastric juice, and at the same time of the precipitation of the organic peptic ferment in an insoluble condition like a kind of lake. A similar action may also be exerted by hydrate of alumina upon some of the organic matters of food. From the general nature of the results obtained, it is inferred that not only alum itself is injurious, but that likewise the residues resulting from its use in bread-making must be ranked as objectionable, and that the practice of adding alum should be studiously avoided when the object aimed at is to make wholesome bread.—*British Medical Journal*.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from March 30, 1889, to April 5, 1889.

C. O. at Los Angeles, Cal., reports the death of Lt.-Col. R. H. Alexander, Surgeon U. S. Army, at 11:50 this morning, March 29, 1889. Telegram.

Lt.-Col. Charles H. Alden, Surgeon U. S. Army, Maj. Henry McElderry, Surgeon U. S. Army, Capt. Washington Matthews, Asst. Surgeon U. S. Army, and Capt. James C. Merrill, Asst. Surgeon U. S. Army, detailed as members of Army Medical Board to meet in New York City, May 1, 1889. Par. 5, S. O. 74, A. G. O., March 30, 1889.

By direction of the Secretary of War, the following changes in the stations and duties of officers of the Medical Department are ordered: Major Joseph R. Gibson, Surgeon, relieved from duty at Ft. Lyon, Col., and ordered to Ft. Sheridan, Ill. Capt. A. H. Appel, Asst. Surgeon, relieved from duty at Ft. Sheridan, Ill., and ordered to duty at Ft. D. A. Russell, Wyo. Capt. George H. Torney, Asst. Surgeon, relieved from duty at Ft. Monroe, Va., and ordered for duty to Ft. Brown, Tex. Capt. Samuel Q. Robinson, Asst. Surgeon, relieved from duty at Ft. Brown, Tex., and ordered to Ft. Hamilton, N. Y., for duty. Par. 11, S. O. 77, A. G. O., Washington, April 3, 1889.

Asst. Surgeon R. R. Ball, ordered to Ft. Riley, Kan., for duty. S. O. 36, Hdqrs. Dept. of the Missouri.

Asst. Surgeon R. W. Johnson reports departure for Whipple Bks., Ariz. Ter., March 25, 1889.

Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending April 6, 1889.

P. A. Surgeon E. H. Marsteller, ordered to the U. S. S. "Adams."

E. H. Stitt, of South Carolina, commissioned Asst. Surgeon U. S. N.

M. F. Gates, of Pennsylvania, commissioned Asst. Surgeon U. S. N.

Surgeon J. C. Boyd, detached from the Bureau Med. and Surg. Navy Dept., and ordered to the "Yorktown."

Asst. Surgeon M. F. Gates, ordered to the Navy Yard, Philadelphia.

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine-Hospital Service, for the Four Weeks Ending March 30, 1889.

Surgeon P. H. Bailhache, relieved from duty at Philadelphia, Pa., to assume charge of the Service at San Francisco, Cal. March 28, 1889.

Surgeon H. W. Sawtelle, when relieved at San Francisco, Cal., to assume charge of the Service at Portland, Me. March 28, 1889.

P. A. Surgeon C. E. Banks, when relieved at Portland, Me., to assume charge of the Service at Vineyard Haven, Mass. March 28, 1889.

P. A. Surgeon R. P. M. Ames, when relieved at Vineyard Haven, Mass., to assume temporary charge of the Service at Philadelphia, Pa. March 28, 1889.

Asst. Surgeon G. M. Magruder, when relieved at Louisville, Ky., to proceed to Memphis, Tenn., for temporary duty. March 28, 1889.

Asst. Surgeon J. B. Stoner, to proceed to Pittsburgh, Pa., for temporary duty. March 28, 1889.

DO MATERNAL IMPRESSIONS AFFECT
THE FŒTUS IN UTERO?

Read before the North Texas Medical Association, Dec. 13, 1888.

BY J. M. FORT, M.D.,
OF PARIS, TEXAS.

We live at a period that will be memorable in the world's history. It is an age of deep and profound thought. An age of unwearied research and investigation; and an age of brilliant discoveries.

All science is achieving grand triumphs, and results that would have confounded and amazed our ancestry of fifty years ago.

Medical science is moving rapidly and grandly forward in this upward and onward march of progress. It is rapidly leaving behind it the dictum of mere opinions and theories which for so many centuries obstructed its progress and misled the minds and wasted the energies of medical men; for, until comparatively a short time ago, theories and speculative opinions were accepted and acted upon by medical men as so many established facts.

It is no easy task to change or alter men's preconceived and long-cherished opinions, but opinions are not always facts, and an opinion unsupported by testimony is but an opinion still. That they are the forerunners of knowledge I admit. They lead the mind far out into the unbounded fields of speculation, seeking to find where truth is hid; but, it is left for experimentation and demonstration, aided by clinical research, reason and analogy to remove the rubbish from off these germs and to expose their hiding places.

Medical science—as all science—“*is the enemy of credulity.*” It challenges reason, invites investigation, stimulates inquiry and welcomes facts, to the end that human life may be prolonged and enriched by health and happiness. It seeks to ennoble, to elevate, and to refine the human race. It seeks to give proper food and shelter, education and raiment, and to inculcate a higher appreciation of health in the physical and intellectual man, and to erect beacons of warning along the dangerous shores of life.

The question which I propose to discuss in this

paper, so far as my investigation and research go, is based solely, and only, upon “opinion or belief,” with an occasional coincidence, unsupported by law or testimony.

“The occasional apparent relation of cause and effect being due in most instances to accidental coincidences, which would be far less frequent if the alleged facts could be obtained prior to instead of subsequent to the birth of the child.”

It is a question which embraces either a widespread error, fraught with human misery and human suffering, a traditional superstition, kept alive, to a great extent, by the medical profession, or it embraces a profound, occult and mysterious law of our being, of which we know nothing, save and except its sad consequences.

The question is: Can the theory of “maternal impressions,” as generally believed and contended for by the great mass of people, and accredited to a considerable extent by learned and scientific physicians, be true?

In other words, can mental impressions or emotions made upon the mind or brain of a pregnant woman, no matter how revolting or disgusting they may be, no matter how horrifying, even if of such a character as to arouse or elicit her feelings to their fullest extent or uttermost depths; or if they be of such a nature as to elicit the tenderest and most sympathetic emotions of her being; or if calculated to excite a keen sense of alarm or fear of impending danger. And if such impressions be made *suddenly, violently*, and should they prove to be lasting in their effects, can these impressions, photographing, as they may, the object or objects making them upon the brain, I say, can they, by or through any known agency, or by any known law, physiological, pathological, or psychological, or by any change which such impressions may make, by nervous shock, in the nutritive element of the blood of the woman, be reproduced in or on the fœtus in utero, or manifest themselves by any abnormality of the fœtus? This is the question. What shall the answer be?

I admit that in a large majority of instances of pregnancy, especially in women of nervous temperaments, the mental faculties act in an exaggerated sphere. They seem to lose for the time being that happy equilibrium and harmony of thought

and action which may have characterized their former lives, and which makes them the charming creatures we know them to be.

The brain does not always give forth a white light, but by perversion the thoughts are made prismatic. They indulge in, or give way to morbid sentiments, and irritable moods, which seem to transform or revolutionize their entire character, passions and prejudices, frequently giving cast to their thoughts and actions. Their desires colored by hopes, or weakened by fears, often warp the judgment and mislead the will. Not infrequently the mind is distorted or, as it were, deformed by morbid apprehensions, and consequently beset with gloomy clouds and dark forebodings of coming evil to themselves or their offspring.

This abnormal mental condition manifests itself in various and frequently in unexpected ways, and when taken in connection with the functional modifications of the nervous system incident to pregnancy, often gives rise to functional disorders of the senses—such as dimness of vision, painfully acute smell, hearing, etc.—as well as to a class of nervous diseases—such as neuralgias, hysteria, vertigo, syncope, and occasionally mania.

As a rule, emotional susceptibility is greatly increased, and a condition of mind, for the most part, exists which readily receives an impression, and as readily perverts, distorts or magnifies it.

These psychical changes and nervous manifestations incident to pregnancy, as every physician knows, are subject to innumerable individual variations.

Now, engraft upon such a mental condition, *if you will*, the belief or opinion that deformity or abnormality to her offspring may result from impressions made upon the mind of the pregnant woman by witnessing certain painful sights or hearing certain distressing sounds, or by permitting the mind to dwell upon certain subjects, especially if of a disagreeable or distressing character, and you most assuredly plant the seeds of gloom and despondency, and give rise to a fearful, yea and a tearful, looking forward to the day of her confinement which such a thought would necessarily and unavoidably produce upon the mind of a sensitive woman.

For permit me to say, that under the most favorable circumstances the pregnant woman looks forward with anxious solicitude to the day and hour when her maternal instincts and motherly yearnings will be gratified. When with feelings *stronger* by far than the *love of life* or the *fear of death* she can clasp in her fond embrace and press to her devoted heart *her own precious babe*, around whom she has already entwined the sweetest, the tenderest, and the most endearing ties and emotions that have ever found lodgment in the human heart.

If, perchance, however, it can be established,

either as a fact or as coming within the realms of probability, that such effects may result from such causes by some mysterious occult law of our being, though inexplicable in the present state of our knowledge, it behooves us as medical men, it behooves husbands, fathers and brothers, it behooves mothers, sisters and friends of the pregnant woman to caution, admonish and to guard her faithfully against every contingency which would even in the most remote degree be calculated to bring about or result in such a sad calamity, for they are the mothers of the race, and when pregnant *woman* appeals to the sympathies, and to the most sacred instincts of our humanity—care for her—be kind and gentle with her, for she is fulfilling a God appointed destiny.

To ask what are "maternal impressions," is but to ask what are intellectual acts, or what are thoughts. It is true, scientists and materialists claim to have answered this question, and perhaps have done so to their own satisfaction, but their answer is far from being received or accepted by the great mass of mankind, and by very many physicians.

That consciousness, or thought, which underlies and is the basis of all knowledge, arising independent of and uncontrolled by the will, is located in and arises from brain matter *no one will deny*. Of all material matter which goes to make up this grand universe, upon which we look with wonder and astonishment, and wherein we find displayed and made manifest to our senses on every hand an infinite wisdom and a creative power far beyond our finite comprehensions, I repeat, of all this wonderful mass of material matter, brain matter, and brain matter only, gives rise to thought. While it is true we can form no idea or conception of thought or intellectual acts aside or disconnected from brain matter and brain action, yet may we not unhesitatingly assert "that physiological research *has not* reduced the fact of intelligence to the phenomena of matter only." "Can thought be evolved by physical or chemical forces or the molecular play of brain matter only?" Physiology cannot or does not affirm the proposition, and yet those who claim to be advanced thinkers assert "that the physical forces of the brain are all sufficient for the production of thought."

One says, "All states of consciousness in us are immediately caused by molecular changes of brain matter." (Huxley.)

Another says, "That the brain secretes thought just as the liver secretes bile." (Cabiness.)

And another says, "That thought is a force developed by brain action."

It is evident from the diversity of opinion here expressed as to *how* thought is evolved from brain matter, that he who endeavors to solve the mysterious connection between mind and matter finds himself walking in a field of obscurity, surrounded on every hand by dark clouds of uncertainty,

which admonish him that there is "a horizon beyond which human knowledge cannot go."

In the dark valley which intervenes between mind and matter, where thought, lost in a labyrinth of mysteries, struggles to comprehend the mode and manner of its own creation, we meet with some of the profoundest mysteries of our nature. Here, gentlemen, we fall in with sleep, dotage, somnambulism, and insanity, mental conditions upon which scarcely a ray of light has been thrown, and around which the veil of mystery hangs like a heavy drapery.

"In the misty clouds of doubt and speculation which forever brood over this dark gulf a thousand theories and a thousand errors lurk."

"In the language of Dr. Theophilus Parvin, we may weigh the brain, count its billions of cells, measure, if you please, the rate of its sensory impressions or motor impulses. You may go further, and localize its functions and analyze its matter, you may convert it into OHNC and Phos., if you wish, you may measure the undulations or vibrations of its molecules, and determine its mechanical or chemical forces and phenomena, and after all of our observations, calculations and analyses" what have we accomplished? We have but *determined the cerebral conditions incident to thought or its production, but not what constitutes thought itself.*

I am fully convinced that every intelligent, thinking physician, every physician who has directed his attention to what are called "mental influences in the causation, the aggravation, as well as in the cure of diseases" will agree with me in the opinion, yea in the *conviction*, that there is something in these bodies of ours superior to the body itself."

I do not believe, therefore, that the phenomena of mental action can be referred to or is dependent on physico-chemical laws, *per se*. "But we must accept the idea of a vital principle as being superphysical, and with that idea, its correlate, a living Creator such principle." "God pervading all, is in all things the mystery of all and each."

So then, in answer to the question, What are "maternal impressions," or what are thoughts considered in their entity? we must, in the language of our esteemed fellow member, Dr. J. S. Sanders, say "we don't know." But while we may not be able to materialize thought, or unravel the mystery of its production, we do know, however, that the brain is so constituted that it can, and does, receive impressions made upon it by external objects though the medium of the senses; or they may originate in the domain of thought itself (as in dreams), through the inherent powers of the imagination, "which worketh while the judgment is at rest and the will is in captivity," and in either event these impressions may become *fixed, permanent, and living images*, ever ready to be called up and brought vividly before the mirror

of the mind, never to be erased so long as the mental faculties retain their normal powers.

Through the medium of language these images or impressions may be conveyed from brain to brain, from mind to mind, *only*, for physiology teaches us that the nervous system—which includes brain and nerves—is anatomically and physiologically separate and distinct from all other systems and organs of the body; that its physiological properties are *inherent*, and that it gives to no tissue or organ its special irritability or power of *performing its particular functions*, *i. e.*, brain matter evolves thought and receives impressions, and nerves transmit them. The power of transmitting thoughts or mental impressions is not and cannot be delegated to any other organ or tissue of the body.

Modern physiology, founded to a great extent upon experiments made upon living animals, teaches us that the intellectual brain; the home of intelligence, the *canvas* upon which these wonderful "maternal impressions" are painted, has far less influence over the functions of the body than at one time was supposed. For instance, it has been demonstrated that, after division of the *dorsal spinal cord*, acts proper to copulation, and those of labor and birth, take place in a normal way, and that the processes of ovulation—of the development of the pregnant uterus—(which necessarily involves the development and growth of the foetus), and the lacteal glands, the development of the impulses which are associated with reproduction, suffer no visible impairment from this operation.

I believe that it is a conceded fact that the umbilical cord, which varies in length from 4 to 60 inches, has no nerves; that is, there are no nerves passing from the uterus of the mother along the cord to the embryo, by which "maternal impressions" could be conveyed to the developing embryo.

Again, we all know that the foetus is surrounded by, and floats in, the amniotic fluid, and that this fluid is developed *very early* in foetal life; that it reaches its maximum quantity about the middle of gestation, and then lessening to the end of pregnancy; so that these "maternal impressions" could scarcely reach the foetal body by or through the medium of its contact with the interior wall of the uterine organs. And since we have shown that the nervous system *never* delegates its peculiar functions to any other organ or tissue of the body; and since it has been determined, and I presume it is conceded by every one, that nerve tissue *only* conveys mental impressions, and as there is no nervous connection whatever, direct or indirect, existing between the organism of the mother and the foetus *in utero*, I again ask how, and by, and through what medium these intellectual impressions are transmitted, or conveyed from the brain of the mother to the foetus *in utero*?

To surmount these barriers to the acceptance of this theory we are told that these impressions may be conveyed in early embryotic life, before the allantois and other membranes form, the placenta and umbilical cord. Before proceeding to meet this suggestion—for it is only a suggestion—I will say that, in a vast majority of instances, it is alleged that these "maternal impressions" operate or exert their deleterious influence upon the fœtus at a later period of gestation; that is, at some period from the third or fourth month of gestation till near the end of pregnancy. As a rule, but little notice is taken of these "maternal impressions," and but little importance attached to them, during the first months of gestation.

The great Creator of all things has ordained from the foundation of the world that man, with all of his capabilities and yet unknown possibilities, should be born of woman. She is the matrix of mankind—the mother and perpetuator of the races; she carries in those wonderful little ovarian bodies of hers the seeds of the human family.

In all the higher order of animals or beings, two separate individual beings are necessary to accomplish the process of germination—one the male, endowed with the fecundating power or nature, and the other the female, endowed with the germinating power or nature. "Male and female created he them, unto the end that they might increase, and multiply, and fill the earth with intelligent beings, wonderfully endowed with life faculties."

In the germinal spot or vesicle of the fecundated ovule or egg of the human female, a microscopic object, $\frac{1}{3000}$ of an inch in diameter, is comprised the very commencement of human life. And in the ovum, which is only $\frac{1}{20}$ of an inch in diameter—strange, wonderful and mysterious as it may seem and is—in this wonderful little object there dwell "*physical potentialities, species, race, family and individuality*;" yea, and more, for here we find implanted that wonderfully mysterious and incomprehensible law of *heredity*—a law to the operation of which we owe our being; a law transmitting the physical, intellectual and moral qualities and peculiarities not only of parent and family, but of race and species, from parent to child; a law far-reaching and widespread in its nature and in its operations; "a law in which these distinctive qualities and peculiarities of race, or family, or both, may slumber through one or more generations, to reappear in subsequent ones." In the operation of this law, we frequently find "disease transmitted from one parent or the other to the offspring, and the disease may show or manifest itself in the child, before it does in the parent transmitting it. Or, again, the malady may date back to a grandparent, the father or mother transmitting to their children a disease of which they (the parents) presented not the slightest manifestations perhaps during a long life."

How true are the words of Edgar Fawcett:

"Who sees how vice her venom wreaks
On the frail babe before it speaks;
And how heredity enslaves
With ghostly hands that reach from graves."

When the vital cells or spermatozoa of the male reach the ovule of the female, many of them collect around it, floating in a medium seemingly provided for the purpose. Several of them may, and frequently do, penetrate the zona-pelucida, its outer membrane, but it is left for one, and one only, to accomplish its fertilization.

When this vitalizing cell enters the germinal vesicle of the ovule, in obedience to an inherent reproductive law which pertains to all germ life, it divides itself into two complete and perfect cells, each retaining its distinctive characteristic features. One, the protoplasmic cell formed of a part of the head of the spermatozoon, impelled by an inherent sexual power, goes direct to the protoplasmic cell or germinal spot of the ovule, and these two protoplasmic cells fuse into one, and form the segmentation nucleus of the fertilized egg.

Again, the vital cell formed by the tail of the spermatozoon unites with the protoplasm furnished by the ovule, forming a second joint or combined cell. These two, in connection with a nucleus or cell resulting from the fusion of the remainder of the head of the spermatozoon with the residue of the germinal vesicle of the ovule, forming, as you see, three classes of cells or spheres, called, as you remember, epiblast, hypoblast, and mesoblast. These, in connection with a group of cells which result from the division of the ovum, called "blastomeres," constitute the several groups of cells developed in the ovum—each cell divides, and each of these again divides, and so on until groups of each are developed.

From these several groups of vital cells as I have endeavored to describe them, formed by fusion of the male and female protoplasmic material, *the fœtus, with all of its organs and tissues, is developed.* And this is accomplished by the same process, and in the same manner, that the organs and tissues of the adult are regenerated and maintained—that is, by cell proliferation and modification.

The youngest human ovum of which we have any record, that has ever been seen, was estimated to be twelve or thirteen days old, and it is thought that it requires about that length of time for it to reach the uterine cavity after leaving the ovarian nidus. During the transit of the ovum through the Fallopian tube, and until attached to, or overlapped by, the mucous lining membrane or decidua of the uterus, nature provides it with its own nutrient material. Most assuredly, it cannot be influenced or impressed by "maternal impressions" at this stage or period of its development, since it has no nervous connection with the uterus,

nor does it draw its nourishment from the nutrient element of the mother's blood. And further, at the end of the first month of gestation, the embryo is but a pulpy mass, without fetal form, and only $1\frac{1}{8}$ of an inch in length. The amniotic fluid, however, has been developed, and the embryo can be seen floating therein even before this period.

The process of segmentation, or binary division, is usually completed by the time the ovum reaches the uterine cavity, by which time a heterogeneous mass—not of cells, but of groups of cells, is formed; each group being endowed with an inherent capacity to form by multiplication and coalition certain organs and tissues of the fetal organism—that and no other. They are the architects and builders of the new being, acting wholly independent of nerve influence from any source whatsoever.

To demonstrate more fully and forcibly this inherent cell law, I here show you the picture of little Ada Hurst, aged two and a half years, from whom I assisted Dr. I. F. Hooks, of Paris, one of our respected and honored members, in removing a dermoid tumor weighing $7\frac{1}{2}$ lbs. One of the ovaries of this child, from some unknown reason, caught up the process of cell multiplication or proliferation, and set to work to make a fetus of its own; the effort resulting in a confused and conglomerate mass of fetal tissue, including hair, bones, etc.

By the operation of this law there is implanted in the ovum everything necessary for the development and growth of the fetal organism, except, perhaps, the nutrient material out of which the process is to be accomplished. The Deity, in his infinite wisdom, has seen fit to isolate these new beings, and place them out of the reach of influences calculated to mar their being or prove hurtful to their development and growth.

To sustain the theory of "maternal impressions" we are further told, that these severe mental emotions so impress, alter, and change the nutritive element of the blood of the mother, that it perverts and vitiates the nutritive process of the fetus; that the fetus, being in the formative stage, is more readily affected by a vitiated or hurtful element of nutrition than the adult.

Upon the point of fetal nutrition I will say, that it has been recently reasserted that the fetus is nourished altogether by swallowing, or absorbing, through the skin, the amniotic fluid, and that the only function of the placenta is to act the part of a lung; that is, to give off the dioxide of carbon from the fetus and to receive oxygen from the arterial blood of the mother, in the same way and manner that the fimbriated extremities of the gills of the fish receive it from the water which it breathes.

If this theory prove to be true, then the fetus supplies its own nutrient material, since the amniotic membrane is strictly a fetal membrane, formed within the ovum in very early embryotic

existence, whose physiological function is to furnish the liquor amnii. This fluid being a secretion furnished by the amniotic membrane, it is more than improbable that maternal impressions could pass through the process of secretion and reach the fetus through such a circuitous route. If, however, it receives its nourishment from the arterial blood of the mother—which it unquestionably does—and these maternal impressions produce a systemic or nervous shock which so alters and changes the nutritive element of the maternal blood as to render it unfit for fetal nutrition, *why not for maternal nutrition as well?* since, for every ounce of this material which is appropriated to the development of the fetal organism, from 2 to 3 lbs. of the same material goes to the regeneration or maintenance of the organism of the mother.

The pregnant woman who maintains her normal physical condition during pregnancy appropriates to the maintenance of her own organism not less than 30 lbs. of nutrient material per month; aggregating 270 lbs. during the period of gestation, and if the child at birth weighs 9 lbs., which is something over an average, the mother will have used *thirty pounds* of the nutrient material, to the fetus' *one*. Further, if the process of nutrition can be deranged, perverted or arrested by impressions made upon the mind, it occurs to me that it would occur more frequently in the mother than in the fetus, since she is in possession of a *matured* nervous system, which it is claimed regulates the functions of secretion, nutrition, calorification, and all the processes of organic life.

It is not claimed, however, that the entire organism of the fetus suffers from this altered condition of the circulating medium of the mother. If such was the case, and "maternal impressions" proved detrimental to the development and well-being of the fetus, we might very rationally conclude that such ill effects were the result of a vitiated or depreciated condition of the nutritive element of the blood. On the contrary, however, their evil effects are only seen in some certain *locality, organ, or tissue*, making manifest such alteration or perversion of the normal process of nutrition by reproducing, on the fetus, a duplicate of the *picture* impressed, or photographed, on the mind of the mother. In other words, these cruel "maternal impressions," as though capable of exercising a degree of intellectual control over the fetal nutritive process, *say to it*, "See that thou makest it" (the picture); it may be a bloody hand, a lacerated and bleeding limb or a deformity of some kind, or a snake, or a turtle, or a rat or mouse, or some other scary animal or ugly sight—it *matters not what*, just so it makes a "maternal impression"—"see that thou makest it according to the pattern showed thee in the mount."

What a wonderful perversion of nature's laws. As an argument in favor of this theory, we are further told that the fœtus is being rapidly developed, that it is in the formative stage, and consequently, any slight alteration in the nutritive process would be followed by more serious results in the fœtus than in the adult.

In answer to this I would say, that it is a well-known fact that, in a large majority of cases of pregnancy, nature provides for the development and growth of the fœtus, by inaugurating in the system of the woman an exaggerated or hypernutritive process similar to that which takes place in the fœtus. This is made apparent by an increase of weight, by an increase of adipose tissue, and by a general improvement in the physical condition and appearance of the woman. This increase of tissue being as newly formed, and as recently developed, as the organism of the fœtus, I can see no reason, nor do I find any medium through which nature could make such cruel and unfair discrimination against the innocent unborn, upon this ground. It seems strange to me that whatever of evil effects or disastrous consequences flow from these "maternal impressions," or mental shocks, that they should be visited on and manifest themselves only upon the fœtus *in utero*.

Again, if the fœtus *in utero* is to be regarded during its development; that is, during its intra-uterine life, as a part of or as an addendum to the physical organism of the woman, subject to all the mutations for good or ill that may take place in her organism, governed and controlled by the same physiological laws that sustain vitality and govern the animal functions, including the nutritive process in the body of the mother; I say, in that event, "maternal impressions" or intellectual acts are most assuredly *inoperative*, and cannot be regarded as instrumental in the production of changes in the developing fœtus to the extent of producing abnormality, for it is well known, nor is it claimed by the most ardent advocates of this theory, "that the Ethiopian can change his skin or the leopard his spots." "Or which of you by taking *thought* can add one cubit to his stature."

If the intellectual impressions can "mark" or deform the fœtus, then they can "mark" or deform the body of the mother as well. As before intimated, I regard it as an unsettled question, as to what extent the process of nutrition is influenced or controlled by nervous influence, or nerve force. In muscular atrophy, for instance, the shrinking and wasting of the muscular tissue is said to be due to inaction; or, in other words, to the loss of motor power, and not to loss of nerve force by paralysis.

I am convinced that the nutritive process going on in the fetal organism is in no wise influenced by its own nervous system. This, I think, is

clearly demonstrated by the perfect development of the acephalic monsters. Some of these are perfect specimens of physical development, *less the brain*. I have in my possession a *finely formed male child*, an anencephalic monster, which is destitute of brain and spinal cord. And yet, some of these have been known to live for from a few hours to six and seven days. Bayle reports one that was born with two teeth, which lived seven days. Ramsbotham reports seeing one of these anencephalic monsters alive thirty-six hours after birth. He states that it cried, sucked, and seemed to perform all the animal functions much more perfectly than would have been supposed. He also relates an instance of a woman having had six children and each alternate one being an anencephalic monster.

It would extend this paper to too great length, and unnecessarily consume the time, to even attempt to enumerate the different abnormalities which have been classified by writers upon this subject, to say nothing of those which have not, running as they do over an extensive field of observation, from the proverbial "strawberry mark" to the composite monstrosities.

In the classification of the hæmiterata, or anomalies of growth alone, we find fourteen varieties described; in the single monstrosities ten varieties; in the twin or composite monstrosities twelve varieties. Then again, each of these varieties are subdivided, extending the list to great length. In the field of malformations or deformities we find an extensive variety, such as bow-legs, knock-knee, bandy-legged, hump-shoulders, all the varieties of club-foot, club hands, supernumerary fingers and toes, cleft fingers and toes, webbed fingers, etc. These are generally hereditary.

"Thus in a family of twelve children two out of four boys had harelip and fissured palate, and one out of eight girls had hypertrophy of the right lower extremity with atrophy of the right great toe. The father had a supernumerary little finger on one hand."

Intra-uterine amputations are not infrequent. Skin diseases are more frequent, and are often likened to the skin of some animal seen by the mother. Congenital nævi are very frequent. This is the disease which makes the "marks" on the new-born babe, and which is contorted into the likeness or image of such a variety of objects by the imagination of old women and doctors, and attributed to "maternal impressions." When arterial and cutaneous they are of a bright florid color, and are made to represent some bloody scene, if, perchance, anything of the kind should have been seen by the mother during gestation. Where venous and cutaneous they are of a bluish or purplish color, and are then made to represent another series of objects.

This disease of the capillaries though generally congenital, may occur after birth. It may

be single or multiple, cutaneous or subcutaneous, arterial venous or mixed. If it was in the human family *only* that these abnormalities occurred we might be inclined to attach more importance to this prevalent idea, but they are of as frequent occurrence if indeed not more frequent in the lower order of animals, especially in the domestic animals, such as the horse, the cow, the dog, the hog, the cat, etc. When they occur in these animals they are the counterpart of what we see in the human subject. They are not infrequent in the feathered tribe, also.

It is true, the animals above enumerated are gifted with wonderful instincts, but it is hardly reasonable to suppose that they possess a sufficient degree of intellectuality to be influenced by such sights or objects as is claimed make these maternal impressions upon the mind of the pregnant woman.

In early embryotic life in case the amnion is not lifted from the newly forming skin of the embryo, in consequence of an insufficient secretion of amniotic fluid adhesions form between the body of the fœtus and amnion, and as the amniotic cavity becomes distended the adhesive material stretches and forms bands of greater or less length and thickness. "These adhesions frequently prevent the proper arching over and closure of the body cavities, producing such deformities as *eventration*, *anencephalus*, etc.

Moreover, a developing limb, as an arm or leg, or a hand or foot, may be caught between two of these bands, or may be encircled by one, and as it grows be so constricted as to produce an amputation. The amputated portion of the limb being in the embryotic stage of development is soon dissolved by the amniotic fluid—or it may be accomplished by the limb being encircled by the umbilical cord. Amputations in-utero occur in this way, and not as a result or consequence of "maternal impressions," as some believe.

In conclusion, I would say that various causes have been assigned for the production of these abnormalities. Some physiologists are inclined to the opinion that the germ is imperfectly formed prior to impregnation. Others that they may result from an undue admixture of protoplasmic material at the moment of fecundation. Other causes also, it is thought, may operate, such as the rapid and active growth which develops from a single cell—in the short space of nine months—one of the most intricate, complicated, complex and mysterious beings in all the animal creation. When we remember that the most important vital functions of this being are performed during its development by an organ itself *without* the fetal body, and subject to diseases and accidents, and when we consider that the fœtus is essentially a parasitic being, liable to become diseased and development arrested by some systemic disease of its host. And again, that these results may be

brought about by some taint or vice handed down from somewhere along its long line of ancestry, even from "Ghostly hands from graves." I repeat, when we take all these things into consideration—and many more which could be mentioned—and then remember that hundreds, if not thousands of children are born every hour, may we not rather be surprised at the comparatively few abnormalities we meet with. And may we not rationally conclude *that there are causes* enough operating to account for their occasional occurrence—which appear more rational and more in harmony with the laws of cause and effect—than to attribute them to the intellectual acts or mental impressions of the pregnant woman. For it is well known that these so-called "maternal impressions" exist to a greater or less extent in the minds of a large majority of pregnant women without producing any visible effects whatever upon the child.

CONSTITUTIONAL TREATMENT OF ACUTE CATARRH OF THE UPPER AIR PASSAGES.

*Read before the American Rhinological Association at Cincinnati,
September 13, 1888.*

BY J. G. CARPENTER, M.D.,

OF STANFORD, KY.

Acute catarrh or cold of the "upper air passages" might truly be called a "fresket" or "overflow" of the watery and other constituents of the blood, into the mucous and submucous connective tissue. To successfully treat this disease, there are three indications, viz.: first, to arrest it in the first stage, or prevent this overflow and injury to the normal tissue; second, should the disease have passed into the second stage, drain out and deplete the engorged and inflamed tissue and arrest inflammation; third, repair the damage to the affected tissue by the disease having passed into the third stage, and not allow it to end in chronic catarrh, but resolution.

Constitutional Treatment.—Bromide of potassium diminishes reflex irritability and cutaneous sensibility, and depresses the activity of the spinal cord and the medulla, and has its appropriate place in the first and second stages of acute catarrh. The iodide of potash acts specifically on the mucous lining of the eyes, nose, frontal and ethmoidal sinuses, mouth and salivary glands; 3 to 10 grs. taken at bedtime will often cut short a cold in the upper respiratory tract, and is indicated in the first and second stages. Combined with 20 or 30 grs. of the bromide its action is increased; in addition, there is the anodyne effect of the latter.

"Inhaled or taken by the stomach camphor exerts a decided influence on cold in the head." Employed at the beginning of an attack (it is useless after the first stage), camphor sometimes arrests a cold, and failing in this it abates its vio-

lence, obviating or diminishing frontal headache, restlessness, sneezing and running at the nose. ("Inhalations or sprays of spts. of camphor locally, in weak solutions, assists the internal administration." Ringer.) The same may be said of menthol in weak solutions, or the pencil applied to lips, tongue and nares.

The hot foot-bath, given in ordinary colds by patient sitting on the side of the bed in a warm room, with a blanket enveloping both patient and tub, for fifteen to thirty minutes, keeping the temperature of the water 95° to 100° F., and then remove feet wrapped in the blanket without drying, causes a free perspiration, and allays irritation of the air passages and restores the skin to its normal function.

Should an acute catarrh or "cold" be very violent, the patient should be placed in bed between two blankets with sufficient cover, and have placed between the blankets a tub of as hot water as can be tolerated, in which the feet should be immersed from twenty minutes to one hour, and tub then removed. Every five minutes a cup of hot water should be added to maintain the high temperature of the bath. The good effects of both a foot and vapor bath are obtained. The patient sweats copiously, and should remain carefully wrapped until the perspiration subsides, the clothing and skin are dry; then the body should be massaged and anointed with vaseline once or twice every twenty-four hours for one or more days, if necessary. The function of the skin being arrested in acute catarrh, the inunction and massage cleanses the skin, invigorates the body, and fortifies the system against future invasions of acute inflammation of the upper air passages. If essential, the hot foot and vapor bath may be given every six or ten hours. A cup of strong hot coffee or tea, or even hot water taken, aid the diaphoresis; the former also acting as a fine diuretic. A hot lemonade or Dovers powder will also increase or continue the diaphoresis for some time after the tub is removed. If a cold is neglected it ends in chronic catarrh, or the subacute. Every cold weakens the system to a certain extent, and makes the patient more susceptible to future attacks unless properly treated, therefore abort or arrest an acute catarrh at once. ("At the commencement of a feverish cold a Turkish bath will cut the attack short, remove the aching pains and relieve the hoarseness at once. The Turkish bath will relieve or carry off the remains of a severe cold, as hoarseness, cough with expectoration and lassitude." Ringer.) In mild attacks of acute catarrh, anointing the integument with vaseline, and the free use of massage once or twice in twenty-four hours for one or more days, will abort an attack and assist the other medicines in accomplishing the same result.

Opium and its preparations check the secretions from all mucous membranes, and no doubt have a

specific effect in checking the acute inflammations and secretions of the upper air passages, and by allaying pain and cutaneous irritation and its diaphoretic action makes it or some of its preparations a valuable, if not the most valuable, drug that can be given in any stage of acute catarrh, more especially in the first and second stages. Opium should be given in $\frac{1}{4}$, $\frac{1}{2}$, or 1 gr. doses, and repeated every one, three or six hours, *pro re nata*. The various preparations should be given in small doses and repeated at the above intervals. It is often essential to combine quinine or belladonna with opium, one or both; the former in 2 to 5 gr. doses; the tincture of belladonna, gtts. iv-xv; extract, $\frac{1}{8}$ to $\frac{1}{3}$ gr., given at the same intervals as opium. When Dovers powder is given the bromide of potash should be substituted for the sulphate. Muriate of pilocarpine, gr. $\frac{1}{4}$ to $\frac{1}{2}$, will aid very materially the diaphoretic action of opium and arrest congestion of the respiratory tract. In the first stages of acute catarrh, nitrite of amyl or "glonoin" will often abort or arrest the disease. The most characteristic effect of this drug is its influence on the vascular system. It relaxes the whole arterial system and greatly reduces arterial pressure. The reduction of arterial pressure is due mainly to the great dilatation of the arterioles and, after large doses, to depression of the heart. Though it dilates the arterioles, they remain so a much shorter time than the arteries, and when the following symptoms are present in the first and second stages, viz.: chilliness, headache, lassitude, dryness of skin, cold feet, sneezing and photophobia, pain in the nasopharyngeal chambers, nitrite of amyl does good by flushing the integument and increasing the heat and perspiration of the head, face and neck; sometimes the increased warmth and perspiration affects the entire skin. Its effect is possibly due to its effect on the vaso-motor nerve trunks or on the muscular coats of the arterioles. In catarrhal, as in other inflammations, there is partial or complete paresis of the vaso-motor constrictors. The nitrite of amyl does not increase the paralysis of the constrictors of the vessels, but dilates the arteries and arterioles and allows circulation of the blood to be increased in other parts of the body, thereby equalizing the circulation and arresting inflammation. Trinitrine tabloids are preferable to the nitrite of amyl. The physiological effects of the former are continued a much longer time than the latter, and four to six doses, three to six hours apart, in twenty-four hours, maintain the physiological effects. Quinine is partly eliminated by the skin and respiratory membrane, and it arrests the amœboid and allied movements of the white corpuscles and is supposed to control inflammation by its destructive influence on the movements of the white corpuscles, and in the first and second stages of acute catarrhal inflammation will cut short an attack. Its action is

much increased by combining it with opium, belladonna or aconite. Quinine, by arresting the transmigration of the white corpuscles, prevents the formation of the pus corpuscles, and should be continued through the third stage of acute catarrh until resolution is complete. It is antiseptic, and in small quantities destroys septic germs, arrests putrefaction, renders the secretions aseptic, and is a valuable local application in the first, second and third stages of acute catarrhal inflammation of the upper air passages. A powder composed of quinine sulph., grs. ij; bismuth subnit., grs. ij; morphine sulph., gr. $\frac{1}{8}$; cocaine muriat., gr. $\frac{1}{8}$ to $\frac{1}{4}$, well triturated and blown into each nostril two or three times in 24 hours, will abort or arrest a cold quickly in the first and second stages and shorten the duration of the third stage.

Belladonna is one of the most efficient drugs that is used in the treatment of acute inflammations of the "upper air passages," and, given internally or locally, checks and even suppresses the secretions of the mucous glands and follicles.

"One of the centres of the sympathetic nervous system—the sphenopalatine ganglion—supplies branches to the lining membrane of the nose, throat, soft palate and Eustachian tube. It possesses a sensory, a motor and a sympathetic root. It is connected with the pneumogastric and facial nerves, and through its numerous connections an intimate sympathetic relation is established between the nose, throat, ear, larynx and bronchial tubes. Removal of this ganglion causes a severe catarrhal condition of the nasal mucous membrane. This membrane is continuous with that which lines the nasal duct and eyelids, the throat, Eustachian tube, middle ear, larynx, trachea and bronchial tubes. A congestion started in one portion of this membrane may extend to other parts." In acute catarrh there is, doubtless, a paresis of the sphenopalatine ganglion and other vaso-motor nerve centres. Belladonna acts specifically upon these centres which supply the glands and follicles of the mucous membrane. It not only arrests the normal supply of blood, but also an excess of blood to the inflamed tissues, and, by dilating the arterioles and arteries in other parts of the body, causes a determination of blood from the tissues involved, arresting inflammation, aborting the first and second stages of catarrh, and lessening the duration of the third. The physiological action of belladonna and its alkaloids is to cause a dryness of the Schneiderian membrane, pharynx, palate, tongue, larynx and trachea. In the second and third stages of acute catarrh this is a great desideratum. The effects of belladonna and its preparations are much increased by opium. Dose of the tincture of belladonna is grs. viij to xv for first dose, then gtts. iv to viij, repeated every two, four or six hours *pro re nata*.

"The power of aconite to control inflammation

and subdue the accompanying fever is remarkable. It will sometimes cut short an inflammation but will not remove its products, though by lessening inflammation it will prevent their formation, so saving the tissues from further injury." It is, therefore, in the early stages of inflammation more conspicuously serviceable, as in the first and second stages of acute catarrhal inflammation of the upper respiratory tract. "Aconite diminishes both the sensibility of the terminal ends of the nerves supplying the mucous membrane and the skin also. Moderate doses lower the pulse and respiration by its influence on the muscular substance of the heart or on the contained ganglia, and on the respiratory centres." Aconite increases the flow of blood to the skin, rendering a dry skin moist and perspiring; in this way heat is lost by radiation and evaporation. Fothergill states, aconite dilates the arterioles and greatly increases the capacity of the vascular system, and by this means drains the blood away from the inflamed organ; in fact, this drug bleeds the patient into his own vessels. As the vessels are already paralyzed leading to an inflamed organ, aconite does not augment the supply of blood to it.

In the first stage of acute catarrh, when rigors, a dry hot skin, dry mouth, tongue and nares, headache, pain in throat or nasal region, restlessness, lassitude, aching pains and stiffness, and photophobia exist, the quickened pulse and respiration become less frequent, and the temperature lowered, by the use of aconite in from six to forty-eight hours, and remain normal; in a few hours the skin becomes moist, and followed in a short time by free perspiration. On rhinoscopic and laryngoscopic examination it will be observed that the local manifestations of acute catarrhal inflammation will have subsided as magically as the constitutional.

How should aconite be given to have the desired effect? It must be given at the inception of the disease; every hour delayed is so much valuable time lost, as the malady will soon pass from the first to the second stage, or from the latter into the third. Half to one drop of the tincture should be given every ten minutes for two hours, in a teaspoonful of water, then hourly; or two or three drops every half to one hour for two hours, then every two or four hours. When there is a weak pulse and much prostration small doses must be given at longer intervals. Ringer states that in the treatment of inflammations the thermometer and aconite should go hand in hand. No acute inflammation can exist without preternatural heat. If the temperature is normal aconite is not indicated, otherwise it should be given. When the catarrhal inflammation is quite severe it is better to combine aconite with belladonna, both given in small doses frequently repeated.

In acute catarrh attended with much preter-

natural heat, headache, myalgia or orbital neuralgia, antipyrin in from three to five or ten grain doses, repeated every one or three hours, has proven to be a valuable addition to the physician's armamentarium of drugs.

Cold compresses to the throat when pain exists or deglutition is painful, and changed every hour until pain is relieved, or cloths wrung out of hot water and applied every ten to thirty minutes until pain is relieved are valuable local measures. When a rhinitis, or naso-pharyngitis exists, with orbital neuralgia, headache and photophobia, great relief is given by local applications to temples and forehead of menthol, either with the pencil, or menthol 5j-5ij, ethyl bromide or alcohol 5ij-5iv, made into a solution and painted over the pain. Should a catarrhal laryngitis or trachitis accompany the naso-pharyngitis, menthol applied over larynx and trachea in the first and second stages of inflammation, every four or six hours, or in the third or purulent stage blisters the size of a nickel over the larynx and trachea very materially hasten resolution. Catarrhal patients must be taught by the physician the importance of resorting to constitutional and local measures when a cold supervenes, and to abort it at once and hasten resolution, and the remedies to be used and always kept on hand. The patient when properly educated can abort a cold in from six to twelve hours when treatment is begun in the first stage, and can check it in from two to four days when begun in the second stage, and lessen the duration of the third stage.

Local Treatment of Acute Catarrh, or Cold, of the Upper Respiratory Tract.—Local treatment has three objects in view, viz.: 1st, non-irritation; 2d, thorough cleansing of the diseased surface with sufficient force to remove the morbid secretion; 3d, medication of diseased tissue without irritating or treating healthy tissue.

(In treating locally acute naso-pharyngeal catarrh the old adage, "*ubi irritatio, ibi fluxus*," must be kept in mind by both patient and physician.)

Treatment of the first stage should be as follows, viz.: Spraying the nasal chambers, or these and the throat, with a 2, 4, or 6 per cent. solution of muriate of cocaine, gtt. 10-30, one to three times a day, at intervals of eight hours, or absorbent cotton saturated with it and inserted into the nares and repeated every ten to thirty minutes until the desired effect is produced. Or, a 2, 4, or 6 per cent. mixture of cocaine can be made with vaseline and sprayed, after being warmed and melted, into the upper respiratory passages. Cocaine is an anæsthetic, anodyne, astringent and antiphlogistic. Vaseline is a mild, soothing astringent, antiphlogistic and aseptic, moistens the mucous lining in the first stage of acute inflammation and protects it against further injury. In this stage the mucous secretion is almost, if not en-

tirely, arrested for the time. Bosworth states there is poured out on the nasal mucous membrane in health from twelve to sixteen ounces daily of serum. This normal secretion is not perceived in health, being rapidly vaporized by the to and fro current of respired air. Doubtless there is equally as much secretion from the pharynx, larynx and trachea in health. When these organs are inflamed, in the first stage of acute catarrh, this secretion is arrested, and vaseline supplies its place and is either absorbed or oxidized, anyhow it is non-irritant, soothing and protective. Liquid applications to an acutely inflamed mucous membrane causes it to absorb moisture and the disease becomes aggravated, cocaine used locally will check a cold in from one to three days, and relieves hyperæsthesia, pain and reflex irritability at once. All local applications should be made with vaseline for the base, melted and liquefied, and sprayed while warm. Equal parts of vaseline and glycerine are very effectual in the first stage of catarrhal inflammation.

Very often acute naso-pharyngeal catarrh is attended with a catarrhal laryngitis, or laryngo-trachitis, and of all means that have been invented for making local applications to the air passages, Rumbold's spray-producers, Nos. 1-5, inclusive, for the naso-pharyngeal chambers, and 6-8 inclusive, for the larynx, are the best, excepting, only, Dr. A. DeVilbiss', of Toledo, Ohio. His spray-producer, by turning a point, can throw the spray in the same number of directions as the Rumbold instruments. With these spray-producers the medicine can be applied warm, the temperature of the respired air, and directly to the diseased surface, healthy tissue being avoided. Not more than 7-10 lbs. of compressed air should be used to make the spray, more than this will cause irritation and pain. A rhino-laryngoscopic examination should be made before each treatment, to ascertain what part of the respiratory tract requires the most treatment, so that the surface least affected will receive the least treatment, and *vice versa*. Every physician should be able to make a rhino-laryngoscopic examination, and know by inspection the pathological states of diseases affecting the upper air passages. On entering the practice of medicine the young physician should get a laryngoscopic "outfit," and familiarize himself with it, as it will be more frequently resorted to than any other instrument in his office. Rumbold's tongue-depressor is the best as it enables the patient to hold down his tongue and gives the operator the use of both hands.

In the second and third stages of acute catarrh the following medicaments are the best:

R	Vaseline	5j
	Olei eucalypti	gtts iij
	Acidi carbol	grs. ss-ijj
	℞	ft. mass.
	Sig. melt and spray 5j-5ij.	

R	Vaseline	3ij
	Pino Canadensis (Kennedy's)	3 ⁴ to ss
	Olei eucalypti	gtts ij-v
m	ft. mass.	
	Sig. melt and spray half to two drachms.	
R	Vaseline	3ij
	Glycerine	3ss
	Acidi carbol	grs. ss-ij
m	ft. mass.	
	Sig. Dose 3ss-3ij.	
R	Vaseline	3j
	Iodol	grs. v-x
m	ft. mass.	
	Sig. Dose 3ss-3ij, melted and sprayed warm.	

The indications in the second stage is to check morbid secretion, render the parts aseptic, allay irritation, and absorb the inflammatory products. The treatment of the third stage is a continuation of the second, but since there is a muco-purulent or a purulent secretion, and abrasions from exfoliation of the epithelium exist it behooves the physician to use locally aseptic and antiseptic measures which have protective and rapidly-healing virtues. Mild solutions of nitrate of silver, grs. ij-grs. v, aquæ 3j, dose, $\frac{1}{2}$ to 2 drachms, or weak solutions of bichloride of mercury, 1:5000, or 1:10,000, or tincture of iodine 3ij, glycerine 3ij-3iij, or Listerine 1 part, water 4-8 parts, glycerine 1-3 parts, should be warmed and sprayed to cleanse and medicate the catarrhal inflammation, followed by a vaseline spray. Insufflations of bismuth subnitrate or powdered yellow root grs. x-3ss combined with powdered lycopodium 3ss after vaseline is sprayed, assists in the protection of any erosion and hastens resolution.

THE PATHOLOGY AND DIAGNOSIS OF SO-CALLED PELVIC CELLULITIS, WITH SPECIMENS OF SALPINGITIS.

*Read before the Section for Clinical Medicine, Pathology, and Hygiene
of the Massachusetts Medical Society, Dec. 12, 1888.*

BY E. W. CUSHING, M.D.,
OF BOSTON, MASS.

Few diseases present a more constant and well-defined group of symptoms, both objective and subjective, than the inflammatory affection of the pelvic contents which is so well known under various names. In few diseases has the proper comprehension of the pathology, as derived from autopsies, been so long obscured by notions supposed to be founded on physical examination; in none has a just realization of the essential nature of the disease been followed by so brilliant and successful surgical measures.

Curiously enough, from early times there have not been wanting accurate descriptions of the diseases of the Fallopian tubes, as found at autopsies, but these were supposed to be affected as a consequence of pelvic inflammation, rather

than as being the essential and causative factor of the latter. It required the surgical genius and success of Tait and Hégear to bring the profession to realize that the diseased and swollen tubes, involved in a mass with ovaries, lymph, and perhaps pus, as described so accurately by Bernutz and Goupil in 1857, are verily the same lumps and "effusions" which we are all continually encountering in pelvic inflammations, and which under the teachings of eminent authority have been supposed to be outside of the cavity of the peritoneum, between the folds of the broad ligament, a supposed inflammation of cellular tissue, forming a so-called "pelvic cellulitis." Verily a case of *lucus a non lucendo*.

Perhaps it will be worth while to pause here a moment and enjoy the pleasure which delighted the pedantic Wagner, that of transporting ourselves into spirit of other times and observing how wise men have thought, in order to mark our own progress:

"Es ist ein gross Ergetzen
Sich in den Geist der Zeiten zu versetzen
Zu schauen wie vor uns ein weiser Mann gedacht.
Und wie wir's dan zuletzt so herrlich weit gebracht."

In the first place, it is often supposed that the ancients knew little or nothing of uterine diseases, had no works on the subject and left all treatment of such affections to ignorant midwives.

Nothing can be further from the truth. The most important uterine diseases have always been and always will be clinically the same, although the treatment has improved with the knowledge of pathology, and the advance of surgery due to the introduction of anæsthesia and the enforcement of cleanliness.

How graphic and true is the clinical description of pelvic inflammation by the father of medicine: "If the uterus is inflamed the menses are suppressed, and the vagina is mottled with many fine veins, like a spider's web, the fever is acute and causes delirium, and the menses when they reappear are scanty and unhealthy; if the patient eats anything she vomits, and pain invades the lower part of the abdomen, and the loins, and the patient faints, and shivers through her whole body, but the belly is sometimes hard and sometimes soft, and it is inflamed and swollen."

Then comes the description of the symptoms of subacute general peritonitis, which sometimes ensues, and the severe course of which is described; to this let me add the description of the results of local examination from Mercatus, the court physician of Philip II, of Spain: "If the posterior and superior part of the uterus is inflamed, there is pain in the parts around the navel, and sometimes we see them raised in a swelling, but there is worse pain in the loins and

the excrements are passed from the bowel with difficulty, etc." "If the fundus is inflamed there is acute pain in the lowest part of the abdomen, so that the latter seems unable to bear any touch even externally, and the uterus is usually drawn toward the inflamed place, and this accounts for its os and collum being turned the other way. It differs from an hysterical attack in the ardent fever and intense heat of the part. If the anterior part of the uterus is affected a difficulty of urination or a stillicidium ensues, and there is severe pain in the umbilicus and the parts near and below the latter, and if the finger is placed against the os uteri it feels to the touch hard, closed, hot and retracted, especially if the inflammation is in the uterus itself or in its neck, and by the pain, hardness, and heat you will distinguish this condition from pregnancy.

But if the sides of the womb are inflamed the groins are tense, and the thighs are moved with difficulty and pain, and in some cases the leg on that side limps in walking, etc.

Then follow the symptoms of suppuration, with a graphic description of the severe cases and a description of the various ways in which the abscess breaks, the relief afforded thereby; the treatment with poultices,² sitz-baths, narcotics, vaginal infections, and vaginal suppositories, cotton tampons medicated with emollient and discutient decoctions, cupping and venesections, the latter only when the inflammation does not arise from abortion, nor from severe labor, or if the patient has not lost much blood.

"Universa etenim curandi phlegmones ratio in prohibitione ejus quod fit et ablatione ejus quod factum est constitit" ("For the universal method of treating phlegmons consists in preventing whatever is forming, and removing whatever has been formed.")

If resolution does not come on, suppuration is encouraged by appropriate treatment until it comes within reach, when it is to be opened after the surgical method of *Ætius*, which consists in cutting the integument with a knife and opening the abscess with a hot iron, placing the woman in a position favorable for drainage and washing the cut three times daily.

I have brought here several of my books in which the curious will find how various wise men have considered this subject before us. To understand them it is only necessary to remember that the uterus in general included the os externum or vulva, the vagina or sinus or cervix uteri, the os internum, now called externum, the collum or vaginal portion, as well as the tubes or cornua uteri, so called from the fancied resemblance to the horns of animals, situated on the uterus as the head; of course the tubes were well known before the description of Fallopius

from whom they now take their name. The question naturally arises as to how much better off is a woman with pelvic inflammation now than was one similarly affected in the time of Philip the Second. Probably in acute cases not much better off, as far as medical treatment is concerned. The disease is the same, the therapeutics are the same, except that the surgical treatment is now bolder, surer and better, under favorable circumstances and in the hands of experts.

But it may be said that these old fellows knew nothing of pelvic cellulitis; they laid all the trouble to inflammation of the uterus and its appendages; they did not know about the "areolar tissue."

That is where they were right, and where in modern times the greatest error has arisen. It is only within the last few years that really accurate views have again prevailed as to the nature of pelvic inflammation. That the Fallopian tubes could be diseased and adhere to the ovaries and to other parts has long been known.

In his classical work, which I have here, Fallopius says distinctly that the tubes are never adherent to the ovaries unless as the result of severe disease of the uterus:

"Nunquam observare potui meatus istos seminarios conjunctos cum testibus, nisi uterus male affectus fuerit. . . . Nam si in uno latere adfuit tumor aut cancer ejusdem etiam lateris testis ita contractus et colligatus cum dicto meatus apparuit ut connati simul viderentur, at oppositi lateris sami scilicet testis non ita se habere semper visus est. Sin autem utrumque latus erat affectum uterque meatus pariter conjunctus cum teste arme reperiēbatur, hæque bis ant ter ad summum vidi" ("I have never been able to find those seminal passages (tubes) joined with the testes (ovaries) unless the uterus was diseased; for if on one side there was a swelling or cancer, the ovary of the same side appeared so contracted and adherent to the said passage (tube) that they seemed congenitally united. But the ovary of the opposite healthy side never seemed to be in such a condition. But if both sides were affected each passage was found by me equally joined to the ovary; and this I have seen twice or at the most three times").

De Graaf,³ in his celebrated work, which I show here, figures Fallopian tubes deformed and occluded at their extremities.

After De Graaf, and quoting his work and that of Fallopius, came Rnysch, of Amsterdam, who in 1725 published at immense expense his treasury or catalogue of his wonderful museum. Fortunately I am in possession of a copy, which I have

² Make and apply to the lower abdomen a poultice of fœnugrecum, pinseed, wheat flour, boiled figs, and turpentine.

³ A plate in the same work (De Graaf, "opera omnia," 1678), showing a tubal pregnancy copied from Vassalius, and properly interpreted, is interesting at this time. *Ann. of Gyn.*, December, 1888.

here. In *Anatomical Observations*, 43, 84, and 85, "Adv. Dec.," i. p. 6, Th. ix. 15.

He correctly explains and figures the occlusion and dilatation of the Fallopian tubes and their adhesion to the ovaries, due to inflammatory processes usually following difficult labors, and insists on the consequent sterility. He relates cases of puerperal fever with autopsies where the pelvis was full of foul matter apparently regurgitated or forced through the tubes from the uterus.

He insists on the frequency of inflammatory affections, and consequent great distension of the tubes, which he says he never would have believed if he had not made autopsies on so many women.

I will not take up any more time by quoting these old authors at length, but as they are overlooked in the modern references to the subject, I have thought it well to present their books to-night. It must be remembered that these works were in their time great authority, and were continually studied and quoted; the successors of these authors in Europe have therefore always preserved a just comprehension of the nature of pelvic disease, and descriptions of the various forms of salpingitis are scattered through the works of the pathologists and gynecologists of more recent times.

A very full bibliography of the subject is given by Prof. Wylie at the end of his admirable article on salpingitis in the recent "*American System of Gynecology*," edited by Prof. Mann.

It is needless for me to repeat it here. It is sufficient to say that about 1884, by the writings of Marchal de Calvi, followed later by Nongt (1849), and yet later by West, Simpson, and others, the seat of pelvic inflammation was located in the areolar connective tissue which surrounds the cervix and fills out the broad ligament.

On the other hand, Aran insisted that the masses felt during life and found after death were connected with the uterine tubes. In 1857, and later, and more fully in 1862, Bernutz and Goupil described and explained the real nature of pelvic inflammation with precision and accuracy; by the courtesy of Dr. Sinclair I present their work to-night.

It now seems difficult to understand why their observations did not have more effect on the profession, especially as the discriminating mind of Thomas⁴ very early supported their views with the weight of his authority, while Emmett has always upheld the doctrine of "pelvic cellulitis," and I believe is still unshaken in his opinions.

The popularity of the works of the latter author, the authority of his personal teaching, and the influence of the men who have studied under him, combined with the fact that the doctrine as taught seemed founded on the plain evidence of the sense of touch—all these causes conspired in

this country to smother the truth as taught by Bernutz, until the results of the autopsies described by the latter were supported and emphasized by the results of hundreds, ay, thousands of operations for salpingitis, where the evident "cellulitis" could be felt to disappear from the "broad ligament" as the operator shelled out a pus-tube and ovary from behind the uterus.

It is not always easy to understand what is meant by pelvic cellulitis, but as far as I comprehend the various authors, and as I previously understood the subject myself, it is as follows:

The course of cellular tissue in the pelvis is pretty well known. Something like a year ago I read before the Society, in connection with the subject of tubal pregnancy, a translation from Prandl⁵ of the instructive work of Schlesinger, who, by injections of air and of liquid glue between the folds of the broad ligaments, near the tubes, showed that areolar tissue, loosely connected, ran between the folds of the ala vesperitilionis up along the psoas muscle, inwards around the cervix and between it and the bladder, outward to the inguinal ring and downward between the rectum and vagina. Now this is precisely the course taken by the pelvic collections of pus in seeking for an outlet; and when, on examination of a patient, a mass is found laterally and posteriorly to the uterus, nothing is more natural than to suppose that the hard mass is in the thickness of the broad ligament, and thus entirely outside of the abdominal cavity, below the peritoneum. If the mass enlarges it would be held that the peritoneum lining the cul-de-sac of Douglas is lifted up, still leaving the "effusion of lymph" extraperitoneal. If after death the ovaries and tubes are found diseased, in many cases it was urged that these were bad cases and therefore fatal; that here the tubes or ovaries were affected because they also were between the folds of the broad ligament, and more or less connected, on one side at least, with this areolar tissue. That, however, most cases which are not fatal, and which recover without suppuration, get well because the lymph in the areolar tissue is absorbed.

If the pelvic peritoneum is inflamed, it is held to be by extension of the disease from its point of origin between the folds of the broad ligament, around the blood-vessels and lymphatics.

This, as I understand it, is the doctrine of pelvic cellulitis or parametritis. It is plausible, fascinating, but, as I believe, entirely false, except perhaps in certain puerperal cases, where a rent, extending at the side of the cervix right into this areolar tissue, may become septic like any other wound.

How then shall we explain the symptoms? If the mass or masses which we feel are not in the broad ligament, where are they? If not effusions in the areolar or cellular tissue, what are they? In

⁴ *Diseases of Women*, 2d ed., 1869, pp. 380, 381, *et seq.*

⁵ *Ann. of Gyn.*, February, 1888, p. 224 *et seq.*

answering this I will premise that I am well aware that, in one sense, the tubes and ovaries are between the folds of the broad ligament; but when speaking here of the broad ligament I mean that part of it which comes up to the limit of the side of the tube, or to the hilum of the ovary—regarding these organs as practically in the general cavity of the abdomen, like the fundus of the uterus itself.

I answer, then, that the mass as felt is in the pouch of Douglas, behind the broad ligament, or laterally at the side of the fundus uteri, or even sometimes on one side posterior and on one side anterior to the latter.

What is the mass? It is a distended tube, or tube and ovary, which may or may not be imbedded in a mass of lymph more or less recent. In bad cases there may be pockets of serum or of pus outside the tubes, but yet within the cavity of the peritoneum, above the latter, and roofed in by coils of intestine matted together and lined with lymph, which may form a strong and smooth membrane, a sort of sac for the abscess. If the areolar tissue is entered, it is secondarily while the abscess is finding its way out along the lines above described.

The diagnosis is to be made between this condition, with its various subdivisions, and the tumors proper and cysts which are found in the same locality.

These comprise—distended tube and its complications: hydrosalpinx; hæmatosalpinx; pyosalpinx; tubercular salpingitis; tubal pregnancy; abscess between tube and ovary surrounded by sac; serous collection in pouch of Douglas adjacent to tube and roofed in by adherent intestines; pus-pockets in the same locality as the last, but usually more thoroughly enclosed by a wall of lymph. Tumors or other possible conditions: parovarian simple cyst; parovarian papillomata; small cystic tumor of ovary; small dermoid cyst; fibroid tumors of uterus; fæcal collections; hæmatocele (intraperitoneal). Cellulitis proper: Periproctitis and perityphlitis; psoas abscess, descending; abscess around vermiform appendix, descending; infected wound of cervix and vagina. Inflammation of hæmatocele (extraperitoneal), or of tubal pregnancy (after rupture between the folds of the broad ligament).

The differential diagnosis of the above affections is often difficult and sometimes impossible without an exploratory incision. Very frequently two or more of them are combined; *e. g.*, the chief cause of suffering in a case of fibroid (myoma) of the uterus may be, and often is, a complication with pyosalpinx.

So also a tube in a state of moderate catarrhal salpingitis may, when nearly healed, become the abode of a tubal pregnancy, and this in turn may, by rupture, lead to a pelvic hæmatocele, and to severe attacks of pelvic peritonitis.

It would unduly prolong this paper to discuss elaborately the subject of differential diagnosis, but there is one point in the symptoms or history of the case which always leads us to suspect tubal disease, and that is the occurrence of *fever*. The patient usually can give a very definite answer to the questions, Did you ever have inflammation of the bowels? How long were you confined to bed by it? Did any matter form and break? Then there will be a history of repeated attacks of pelvic pain with fever, of severe and repeated suffering during the menstrual periods, of lameness, backache, etc. Usually or always in old cases there is a history of repeated and fruitless attempts at mechanical assistance: the patient cannot wear any pessary; Drs. A. B. C. and X. Y. Z. have tried to fit pessaries, but they all hurt her, and often she has been very ill after the womb was "raised up with an instrument."

The patient is said to have an adherent retroversion: "her womb is grown on to the back passage," or there is an anteversion or lateral-version.

In severe cases there is a recent history of supuration. The patient is found in bed, with the symptoms described by the ancient authors above mentioned, who, be it said, also describe at great length the hard masses which remain unless the "peccant" matters are properly "concocted" and eliminated. Or there is a fistula, continually or occasionally discharging pus; in the latter case there is usually an account of attacks of pain and fever whenever the fistula closes.

It is very difficult to describe exactly the feeling on bimanual examination; by repeated practice a certain familiarity with the pelvic organs and their relations is acquired which cannot easily be adequately conveyed in language.

The first thing observed is that the examination is painful to the patient. The uterus appears displaced: at first it seems retroverted, but by careful examination it is usually found that the fundus is anteverted and often drawn to one side, showing that the tender mass behind, and lateral to the uterus, must be something which does not belong there.

Now small ovarian tumors, dermoid cysts, and cysts of the broad ligament do not give rise to fever, and are not usually painful to the touch; the same may be said of fibroid tumors when small and sub-peritoneal; tubal pregnancy can usually be excluded, especially in chronic cases; the tumors of simple hydrosalpinx are not fixed but movable, "pelvic cellulitis," *i. e.*, inflammatory effusion between the folds of the broad ligament, is practically a myth; pelvic hæmatocele has a characteristic history and course. Therefore, by exclusion we arrive at a pretty clear diagnosis of salpingitis and consequent localized peritonitis.

Especially is this opinion confirmed when an-

other mass is found on the other side of the uterus, also tender, fixed and chronic. The only double tumors likely to be found on both sides, except distended tubes, are double papillomata of the broad ligaments and double dermoids, both of which, by their lack of fever and tenderness, and by their steady growth, soon differentiate themselves from tubes, and require an operation which settles the diagnosis.

It is often desirable, especially before deciding on an operation for removal of diseased tubes, to examine the patient under anæsthesia; the relaxation of the abdominal walls, and of the muscular floor of the pelvis, and the consequent relief of the pelvic organs from pressure, wonderfully facilitate the examination, which is completed by a rectal examination, with two fingers in the rectum, the thumb in the vagina, and the other hand on the abdomen. I may here observe that great care must be taken not to rupture the pus-tubes nor to squeeze out pus from imperfectly occluded fimbriated extremities. Such an occurrence might easily be, and in fact has frequently been, followed by a severe or even fatal peritonitis.

In such an examination the first landmark to be sought for is the fundus of the uterus; just as in the corresponding operation for removal of the tubes, we start out from the fundus to determine their position, size and attachment. In normal cases, especially under anæsthesia, the tubes can usually be felt at either cornu, forming, with the round ligaments, bodies which feel about as large as lead pencils, which can be rolled, under the fingers, and moved freely about. After an attack of gonorrhœa their increase in size and hardness can often be observed long before acute perimetritic symptoms develop.

In catarrhal salpingitis, where the fimbriated extremities are occluded and the tubes are distended, they can be traced as soft, sausage-shaped bodies at the sides of and behind the uterus, sometimes quite large, but usually freely movable and not very tender to the touch.

In pyosalpinx, however, they are more apt to be fixed by repeated attacks of pelvic peritonitis; the tubes fall down behind the ovaries, as described so well by Wylie, and are glued to them; the left tube generally gets first into Douglas's pouch and keeps the other out; tube, ovary, and effused lymph form a mass of a size widely varying from that of an egg to that of the two fists or larger; on one side this blocks up the pouch of Douglas and presses on the rectum and bulges down behind the uterus; on the other it may lie further forward, even at the brim of the pelvis, where it is readily felt as a lump in the iliac region. If the tubes and the neighboring adhesions contain much pus, fluctuation may be distinctly felt, with the well known symptoms of pelvic abscess; more frequently the mass is hard

or doughy; often it varies from week to week as pus and serum distend the tube and the surrounding pockets, and then are gradually absorbed again.

That is the real nature of pelvic cellulitis, and nothing is more surprising and convincing than to feel from the vagina the disappearance of a mass, supposed to be in the areolar tissue of the broad ligament, as the operator unrolls and shells out a brace of pus-tubes.

It may be said that there is nothing new in all this. Such affections of the tubes are described by Bernutz and Aran, by Kiwisch, and Ed. Martin and Klob, and by many others. That is true; but what is comparatively new is the realizing sense on the part of the profession that the tubal affections are the origin and not the consequence of the pelvic peritonitis, that the former come directly from the passage of infection from the uterus into the tubes. From this last fact results a growing appreciation of the danger of infection from gonorrhœa and from sounds and instruments. The pithy remark of Credé, "that he who does not examine a woman does not infect her," is well worthy of remembrance, both in regard to obstetrical and gynecological work. I purposely say little as to the causes and symptoms of the disease; are they not written in all the books? It is all an infection from one cause or another.

The immense importance of gonorrhœal infection in causing tubal disease, is becoming more and more appreciated, both by the profession and the public, and the erring husband who hereafter infects his wife will receive the execration he deserves. An important duty rests on the members of the profession in duly impressing on men the danger of infecting their wives even after they themselves seem to be cured.

But it will be said that this explanation may suffice for old, chronic cases, which are operated on either for severe inflammatory attacks or for unendurable pain and loss of health. But how about the cases which are "resolved" and get well? How about a woman who "catches cold" after "local treatment" and runs through a course of cellulitis, where there is a mass in the pelvis as big as a child's head at term, the uterus fixed, the roof of the vagina hard? This cannot be a tube, neither is it an abscess, for it does not suppurate, but under expectant and soothing treatment it all goes away.

Now these cases are frequent, and in the first place very many or most of them do not get well entirely, but have a mass of adhesions and a disease of the tubes left, which cause sterility and future trouble. Some do get well, however, and bear children. What is such a mass? Is it not in the areolar tissue? No, the mass is inside the cavity of the peritoneum. It is chiefly one or more serous cysts, bounded by the peritoneum be-

low, and above by adhesions and by coils of intestines. The hardness is caused by involuntary contraction of the muscles, and by tenseness of the cyst; possibly to some extent by an infiltration of the adjacent "areolar" tissue with oedematous fluid; the origin is in the tube and the cause is the "treatment."

Another group of cases too important to be more than mentioned to-night are cases classed as cellulitis which followed labor or abortion. Here again every one, in discussing the subject, admits a puerperal "cellulitis" of the "areolar tissue," but how many are seen post-mortem. Besides the cases of acute septicæmia, thrombosis, etc., when there is peritonitis what is found at autopsy? Just what Ruysch found (Obs. 43, 84, 85) a collection of foul matter in the *pelvis*, the tubes diseased and similar matter in the tubes and uterus. Most of these patients die; although in some the matters are shut out from the general abdominal cavity, a pelvic abscess results which is not between the folds of the broad ligament; if this matter is evacuated the diseased tubes remain, and may give rise to continual trouble afterward. In some cases a condition of comparative comfort results, but the diseased tubes can be detected long afterwards in very, very many cases in women who never recover their health perfectly.

Very lately, Tait has operated on a series of these puerperal cases. He reported eight in June last,⁶ with two deaths. J. Price (and perhaps others) has followed him in this country, having operated, as he writes me, on seven puerperal cases up to the present time, with two deaths. In all the cases there was no sign of disease between the folds of the broad ligament; salpingitis and pelvic peritonitis were what were found.

I saw myself one of M. Price's operations on a woman with pelvic inflammation after abortion, and I shall never forget the hugely distended pus tubes, large as Bologna sausages, which were shelled out, while the pelvis was full of stinking pus in pockets running up between the intestines in all directions; it was, as Ruysch said, "*colluries humorum non sine magno fetore*." Here is a great field in the future for the snatching of women from almost certain death by an operation which, *if not deferred until too late*, offers a good prospect of relief.

MEDICAL PROGRESS.

POISON IN THE BREATH.—MM. BROWN-SÉQUARD and D'ARSONVAL have reported to the Academy of Science the results of new experiments that show the poison or poisons which escape with the breath can become fatal in small quantities, even if not injected directly into the

venous or arterial blood. Injected subcutaneously the fluid containing this poison proved fatal to 17 out of 18 rabbits in doses of 16–44 cc.; in two-thirds death ensued in from 12 to 24 hours after the injection. But even when injected into the rectum and the stomach the liquid may cause death, but this occurred only in 2 out of 7 which had from 24–36 cc. introduced into the stomach. According to these eminent physiologists this toxic power is not ascribable to the presence of microbes in the fluid, for it is equally poisonous after it has been subjected to a temperature of 100°. They consider it certain that the carbonic acid in the breath has no share in its toxic qualities.

The ingenious apparatus which was used for these experiments consists of a number of metallic vessels which were made absolutely air-tight. An air-pump connected with a gasometer sends a continuous current through these vessels, which are connected with one another in such a way that the current of air passes them successively. Thus and animal placed in the vessel into which the outer air enters breathes the pure air, whilst all the other animals placed in the other vessels breathe air more or less vitiated. It is evident that the last animal breathes the air that has passed through all the other vessels, whilst the second animal, for instance, breathes the air of the first vessel only. Each vessel consists of a vertical cylinder of galvanized sheet-iron, large enough to hold a good-sized rabbit; a conical funnel receives the dejections of the animal and the remnants of food and dumps them into an earthen vessel likewise air-tight. Young rabbits (from 5 to 7 weeks old) which were shut up in these vessels died rapidly, except those in the first and second vessel. In some instances the rabbits in the 7th and 8th, and even that in the 6th perished in two or three days. On an average one week killed the animal in the 4th, and a few days later that in the 3d died. The rabbits in the 1st and 2d survived for a long time and finally died accidentally. When a rabbit which was almost dying in one of the vessels, 3, 4, 5, 6, 7 or 8, was taken out it generally revived and regained its health, but only after a long time. The quantity of carbonic acid which was considerably under 1 per cent. in vessel No. 2, was generally but little over 2 or 3 per cent. in vessels 6, 7 and 8. With a more rapid current there was sometimes even less carbonic acid in the last vessels.

"By numerous experiments we have assured ourselves that pure carbonic acid may be inhaled with the atmospheric air in considerable quantities by human beings, dogs, rabbits, and other mammaliæ. We have ourselves been able to breathe from one to two hours in an atmosphere charged with 20 per cent. of CO₂ without being noticeably affected, and especially without any lasting effect.

⁶Ann. of Gyn., June, 1888

"By altering our apparatus through the addition of two supplementary parts we could introduce into the cylinder the air from vessel 6 after it had been subjected to the action of sulphuric acid. The latter takes up the pulmonary poison and the organic substances (whatever they may be) which issued from the first six vessels, whilst the carbonic acid becomes free. The air passing into the two supplementary vessels is therefore free from the pulmonary poison but charged with carbonic acid. Now this air is not fatal, and we possess in this fact a proof, at the same time, of the harmlessness of carbonic acid and of the toxic power of pulmonary poison.

"In these experiments death ensued in the same way as where the liquid was administered subcutaneously or otherwise; painless and almost without convulsions. The autopsy showed that the animal died from the stoppage of the exchanges between the tissues and the blood.

"The question arises whether the death of the animals in these experiments was due to a poison issuing from the lungs. It is easily answered. The symptoms and the condition of the organs after death are the same as those found in animals to which the fluid had been administered subcutaneously or otherwise. That there exists in confined air other causes capable of affecting health we do not deny, but it seems to us, for the reason above stated, that in these experiments death was due principally, if not exclusively, to the breathing of air which had been inhaled and confined for several days.—*Journal d'Hygiène*, vol. xiv, No. 651.

ESCHSCHOLTZIA CALIFORNICA.—In 1887 STANISLAUS MARTIN endeavored in vain, in the *Bull. génér. de Thérap.*, to call the attention of physicians to this plant, which is used as a sedative in some localities. More recently TER-ZAKARIANT, at the instance of Dujardin-Beaumetz, has made an examination of it which resulted as follows: *Eschscholtzia Californica*, of the family of Papaveraceæ, is a shrub-like plant indigenous to North America, and especially common in California, with no less than ten slightly different varieties. (Greene.)

One hundred parts of this plant yield an average of 20 grm. of an alcoholic, resinous, dark-green extract, of a pleasant smell and bitter taste, which is perfectly soluble with alcohol, largely so in water, only partly soluble in glycerine, and insoluble in chloroform and ether. In water 100 parts of the plant yield about 15 grms. of extract. This latter is reddish-brown in color, having the same smell and taste as the alcoholic extract; dissolves in water, alcohol and glycerine, but is insoluble in ether or chloroform.

Bardet and Adrian isolated from the plant a base contained in the drogue in lesser quantity, which they think is morphine, and in larger

quantity, an alkaloid, and a glycosoid. Experiments on animals made with the alcoholic and the watery extract showed that these extracts were effective only in comparatively large doses.

Doses of 2.5 gr. subcutaneously, and of 6.0 gr. internally pro kilo of animal were toxic. Smaller doses affect only the brain, the animal sitting motionless, deprived of will and entirely oblivious to their surroundings. Larger doses affect the medulla oblongata, the spinal marrow and the peripheral nerves. Constant symptoms are: general debility, torpor, acceleration of respiration, subsequent slowing of the same, complete paralysis of the extremities and slowing of the circulation. The sensory nerves are paralyzed after the motor-nerves and regain their sensibility sooner. The body-temperature is increased by the alcoholic-resinous extract and reduced by the extract when freed from resinous substances, by about 1° C.

After therapeutic experiments made with the alcoholic extract on 13 patients (chron. bronchitis, phthisis, morbus brightii, ischias, paralysis agitans, rheumatism), Ter-Zakariant designates *eschscholtzia* as a valuable and harmless somniferous substance, and as an analgesic extremely useful in certain cases, whose effect outlasts the time of its application and is free from the undesirable qualities of morphine. Large doses seem necessary: 2.5 to 10 gr. daily, even 12 gr. have been given.

Further experiments will be necessary to form a conclusive opinion regarding the value of this new remedy.—*Therapeutische Monatshefte*, March, 1889.

MICROÖRGANISMS IN THE GENITAL CHANNEL OF THE HEALTHY WOMAN.—WINTER publishes a careful work in which he attempts to answer the questions: 1, in what parts of the genital channel of the healthy woman are bacteria found; 2, of what kind are they; 3, are any among them pathogenic. In forty Fallopian tubes which were obtained during operations, no microorganisms were found. Of thirty extirpated uteri twenty-two were likewise found free from bacteria, whilst in eight cases they doubtless got into the uterus through previous digital or sound examinations. The cervix examinations made on living individuals showed microorganisms (cocci and bacilli); the latter largely increased in number during pregnancy. The same was true of the vagina. The inner os of the uterus forms, consequently, the border between the parts infested with bacteria and those free from bacteria. As regards the question of pathogeny, the pus cocci (staphylococci) were found in one-half of the cases in the secretions. But the experiments with vaccination proved them to be of lessened virulence, probably being weakened by the secretions of the other bacteria.

Of practical importance is the inference from

these tests that internal examinations of the uterus should be preceded by the most painstaking disinfection of the vagina and the cervix. It is shown that when substances subject to decomposition: blood, ovarian membranes and remnants of the placenta, are present in the uterine cavity, self-infection may take place through spreading of pathogenic germs from the vagina.—*Correspondenz-Blatt für Schweizer Aerzte*, March 15, 1889.

A RARE COMPLICATION IN INTESTINAL TYPHUS.—J. KARLINSKY (*Berliner klinische Wochenschrift*, 1888, No. 43) reports a case of typhus abdominalis in which, three weeks after the beginning of the disease, easily colored bacilli were found in the stools, which were nine μ long, single or arranged in chains of two or three links. In bouillon-cultures mostly 5-10 links appeared in a chain. In some of the bacilli spores could be distinctly seen. Subcutaneous injections of these bacilli killed young rabbits within two days. In the lymph of the animals, as also in the blood-vessels of the liver, the author found the same bacilli—which he takes for milzbrand-bacilli—in large quantities. Besides these microorganisms, streptococci and smaller bacilli were found in the fæces in small quantities. The patient died in thirty days from the beginning of the sickness.

The examination of the lower ileum and of the cæcum showed typical typhus abscesses, in the stomach and the remainder of the small intestine changes were found such as are occasionally seen in milzbrand. In the blood from the liver, in the spleen-veins, the veins on the surface of the stomach, in the spleen-juice, abundant milzbrand-bacilli were found. On gelatine and agar-cultures typical milzbrand colonies developed. The liver, the intestinal wall, and a part of the mesenteric glands contained large numbers of milzbrand-bacilli, whilst in the abscesses in the lower ileum and cæcum typhus-bacilli were found.

The author ascribes the milzbrand infection to the circumstance that the patient on the twentieth day had taken some milk which, as was proven on a searching investigation, had come from a cow affected with milzbrand.—*Centralblatt für Bakteriologie und Parasitenkunde*, Band v, No. 12.

ABOUT THE TREATMENT OF DIPHTHERIA WITH ACID SALICYL.—In a paper read Dec. 5, 1888, by PROF. D'ESPINE, before the Medical Society of Genf, the author explains a mode of treating diphtheria which—based on bacteriological investigations—he has pursued with the aid of Dr. de Marignac. These investigators found that Löffler's bacillus, which they consider as pathogenic for diphtheria, is killed by five minutes' contact with salicylic acid dissolved in water 1:2000. This substance is consequently used in the local treatment of diphtheritic affections of the throat, the false membranes of the naso-phar-

ynx being irrigated every hour or every two hours with a 1½ or 2 per cent. solution of salicylic acid. The irrigation was made through the mouth by means of an irrigator or a pear-shaped syringe, so that a sharp stream of the liquid bathed the false membranes; for the nose it was deemed sufficient to pour tablespoonfuls of the solution into it; from 1 to 2 litres of the solution are to be used in the first twenty-four hours of treatment. The method of irrigation has the advantage of an energetic application of the remedy without causing injury and opening gates for infection. A few hours of this treatment are said to be often sufficient to break up the fever, and after two or three days the throat usually throws off the false membranes. An early beginning with this treatment is of importance; the author recommends, in cases of epidemics of diphtheria, to treat prophylactically cases of apparently simple angina in the same manner.

Even before d'Espine salicylic acid has been used for diphtheria, but the application of large quantities of liquid by means of an irrigator is new, and this mode of application seems to prove very effective in practice. E. Kummer, of Genf, has found the treatment decidedly beneficial in several cases, and invites further experiments.—*Correspondenz-Blatt für Schweizer Aerzte*, March 15, 1889.

CONCERNING THE ETIOLOGY OF PUS-FORMATION.—JUL. STEINHAUS, in the *Zeitschrift für Hygiene*, Bd. V, Heft 3, reports that he found in the contents of an abscess large quantities of the well-known micrococcus tetragenus, whilst the bacteria usually occurring in pus, staphylococci and streptococci, were altogether missing. Steinhaus thinks, therefore, that the micrococcus tetragenus, under certain conditions, might become a cause of purulent processes in man.

The experiments which led him to take this view cannot be considered as conclusive proofs, as he failed to establish such a result through plate culture. Steinhaus made only "two tube-cultures on gelatine" directly from the pus, and thereby made the same mistake which, though often sharply criticised, is repeated over and over again. In the examination of the pus plate-cultures would now show us, perhaps, preponderating colonies of the micrococcus tetragenus, but also here and there some of the streptococcus, and would thus point out the real condition of affairs. In tube-cultures, however, the rapidly growing micrococcus tetragenus strangles the slowly growing streptococcus and deprives it of the ability to make itself known in any way, so that an erroneous conclusion becomes unavoidable.—*Centralblatt für Bakteriologie und Parasitenkunde*, Band V, No. 12.

SATURDAY, APRIL 20, 1889.

INFLUENCE OF CLIMATE ON PHTHISIS.

In THE JOURNAL of last week attention was directed to the reprint edition of DR. CHARLES DENISON's paper on the "Preferable Climate for Phthisis," read in the Section of Demography of the Ninth International Medical Congress, Washington, 1887. Attention was then directed to the chief elements that, in varying combinations, determine the special character of the climate in any given locality. The combination of these elements claimed by Dr. Denison as constituting the preferable climate for patients affected with phthisis is, purity, rarefaction, dryness, coolness, variability, uneven or mountainous surfaces, with gravelly or porous soil. The purity of the atmosphere or freedom from intermixture with foreign ingredients increases with the altitude above the sea level, and according to the observations of Miquel, becomes entirely free from bacteria or organic germs at an elevation above 2,000 metres (ft. 6,560). At 560 metres (ft. 1,700) he found only 8 bacteria to 10 cubic metres of air, while in the streets of Paris, near the level of the sea, he found no less than 55,000 to 10 cubic metres of air. The observations were all made in the month of July, 1883. It may be inferred, therefore, that the higher altitudes are very unfavorable for the propagation of bacillus tuberculosis, as well as ordinary bacteria.

The greater the rarefaction of the air, the less amount of oxygen is contained in a cubic foot, and the more active the respiratory movements become in order to supply the blood with the re-

quired amount of oxygen in a given time. It is this increased activity of the respiratory movements in breathing the rarefied air of high altitudes that tends strongly to expand the chest, and makes it specially beneficial to those young persons with chests flattened beneath the clavicles and plainly predisposed to phthisis, and to all cases while in the stage of primary unsoftened tubercular deposit. But when the capacity of the lungs is already diminished one-third or one-half by extensive tubercular infiltrations in the stage of purulent softening and hectic fever, or by the sclerosis of pulmonary tissue called by some chronic interstitial pneumonia and by others fibroid phthisis, it becomes impossible for the patient to inhale the necessary increased quantity of rarefied air, and persistence in the attempt generally hastens the fatal result. The coolness and dryness of the atmosphere generally increases with the altitude, and are usually found in coincidence with rarefaction. It is a familiar law that the dryer the air at a given temperature the more rapidly will it absorb aqueous vapor from moistened surfaces. Hence if we inhale an atmosphere already saturated with moisture it will return by exhalation in the same condition, having absorbed nothing from the moistened pulmonary surfaces. On the other hand the dryer the air inhaled the greater will be the amount of aqueous vapor and such other matters as may be in solution therein, that will be absorbed and removed with the exhaled air. That Dr. Denison is correct in claiming that cool and variable atmospheric conditions are more beneficial to consumptives and other debilitated patients, than warm and uniform conditions are, we have no doubt. Continuous heat expands the tissues and thereby causes relaxation and debility; while continuous cold constricts or condenses the structures and soon lessens the activity of all the functions. Coolness, with frequent variations within moderate limits, contributes far more to the maintenance of functional activity and strength, and thereby acts in harmony with rarefaction and dryness at high altitudes.

Without pursuing these elementary considerations further, we may suggest the following rules for the guidance of the practitioner in his dealing with the question of climates and phthisis:

1st. Ascertain by thorough physical examination the degree of development of the chest and

the actual condition of the lungs in reference to the existence of tuberculous deposits or other structural changes, their extent and stage of progress.

2. If the patient presents only a narrow chest and defective muscular development without appreciable changes in the pulmonary structures, a residence in the pure, cool, dry, rarefied and variable atmosphere of the mountains at altitudes between 4,000 and 6,000 feet, at almost any point between Manitau in Colorado and San Antonio in Texas, with an outdoor occupation, will be most certain to establish in him a healthy, vigorous physical condition.

3. If the patient is found to have only a moderate amount of crude unsoftened tubercular deposit; or if he has deposit in the softened and suppurative stage limited strictly to the apex or upper part of *one* lung, leaving the other lung healthy, and his total lung capacity for air not diminished more than one-tenth, his chances of recovery will be secured in the highest degree by a residence in the same climatic conditions named in the preceding paragraph. The patients indicated in this and the preceding paragraph will also generally be restored by long sea voyages extending through a wide range of latitude, provided they take such daily exercises of the muscles of the chest and arms as will favor increased capacity of the chest.

4. If the patient is found to have pretty extensive tubercular deposits in both lungs, with distinct indications of commencing softening, the chest capacity for air diminished one-fifth or more, and more or less fever, he cannot be safely sent at once to the high altitudes of Colorado, New Mexico, etc. As pure, dry and mild air as can be found at lower levels should be chosen. The more moderate altitudes found in the mountain districts of North and South Carolina, Georgia and East Tennessee for the summer, and the interior of Florida, southern part of California and some parts of Texas for the winter months, are best suited to such a patient, and will often arrest the further progress of the disease.

5. If, however, a careful examination of the patient shows extensive deposits or consolidation involving one-half or even one-third of both lungs, with suppurative cavities in both, copious purulent expectoration, hectic fever, and extreme emaciation, he should be candidly advised to make

himself as comfortable as possible at his home and with his friends, if he have any, instead of exhausting what little breathing capacity he has left in a vain struggle to reach a better climate and finally perishing among strangers.

6. To whatever climate it is deemed best that a patient should go, if it is found to influence him favorably, he should be strongly advised to take up his residence there from one to five years at least. One of the most important causes of failure to get permanent recoveries by change of climate, is the persistency of patients in returning home and to the same habits and surroundings as before, as soon as the more manifest and troublesome symptoms of disease have subsided; and consequently, in four cases out of five, the disease renews its advancement after a few months.

MILROY'S MEDIO-TARSAL AMPUTATION.

Under this title was published, in *THE JOURNAL* of March 30, in the columns for Medical Progress, the report of a case copied from the *Glasgow Medical Journal*, of March, 1889. The case was one of medio-tarsal amputation performed on account of severe injury of the foot, by DR. MILROY, of Kilwinning, Scotland, September 7, 1885, and reported by him to the Surgical Section of the Medico-Chirurgical Society of Glasgow, January 25, 1889. It was spoken of as a *new* operation, and its advantages compared with those of the operations of Chopart, Syme and others.

Since the appearance of Dr. Milroy's case in this journal, our attention has been called to the fact that an operation nearly identical with it, had been performed several times prior to 1874 by DR. S. F. FORBES, of Toledo, Ohio, and the operation fully described by him in a paper read at the annual Meeting of the Ohio State Medical Society in 1874. The report was published in the Transactions of the Society for that year, illustrated by a cut; and to do justice to Dr. Forbes we renew attention to his work by making the following quotations from his paper. He describes his operation as follows:

"The flaps being made as in Chopart's operation, that is by an anterior and posterior flap, one horn of which should commence on the inner side of the foot opposite the tubercle of the scaphoid bone, and the other terminate on the outer border

or tubercle of the cuboid, and the flaps, being well reflected back, the knife, a stout, straight bistoury, should be entered between the scaphoid behind and the internal cuneiform bone in front, and carried onward between the cuneiform bones and the scaphoid until the cuboid is reached. Twisting the foot well outward with the left hand of the operator will facilitate the movement of the knife along the articulations mentioned. Having arrived at the cuboid the knife should give place to the saw, when the cuboid should be sawn squarely across, and the operation is completed. Should any difficulty be experienced in passing the knife along the external cuneiform the saw can at once be resorted to, and any portion of this bone which may be left in the stump can readily be dissected out. . . .

"By examining the bones of the foot it will be seen that where the scaphoid and a portion of the cuboid is left in the stump (as in this operation I am describing) each bone has a bold prominence or tubercle on its under surface which is of great service to the patient in walking ever after, a point not to be lost sight of by the surgeon."

After describing certain items of after-treatment and modes of dressing, Dr. Forbes sums up the results and advantages of his operation as follows:

"There are several persons in this vicinity upon whom the operation I have spoken of has been performed, when wearing an ordinary shoe with the front filled with cork, whose gait and carriage are so steady that it would be quite impossible for even a surgeon to say upon which limb the operation had been performed. These persons engage in railroading, farming, etc., without crutch or cane, and with so little inconvenience, apparently, as not to notice they have suffered any loss.

"The points I seek to make in this paper are, that I propose an operation which is easier of execution than any other recognized amputation through the tarsus, that the stump resulting is as good as that left after Hey's operation, and that by reason of leaving the tubercles of the scaphoid and cuboid bones it is always better than the stump left after Chopart's operation; further, that the bony column behind the cuneiform bones should never be sacrificed to the demands of coverings except in cases of imperative necessity; and, lastly, that upon the treatment after the op-

eration depends in a great degree the future usefulness of the limb."

The critical reader will observe that Drs. Forbes and Milroy both separate the scaphoid from the cuneiform bones, the former completes the operation by sawing directly through the cuboid, while the latter disarticulates it.

THE ILLINOIS STATE BOARD OF HEALTH AND THE STATE LEGISLATURE.

The House of Representatives of the Illinois State Legislature appears to have developed a decided opposition to the State Board of Health, by striking out of the general appropriation bill all provision for the support of the Board for the next two years, and by a proposition that is still pending, to repeal Section 11 of the Medical Practice Act. This Section is the one prohibiting all traveling or itinerant medicine vendors to ply their vocation in the State unless they obtain a license from the State Board, for which they must pay \$100 per month. From the tenor of the discussions in the Legislature, it appears that the opposition originates mainly from the idea that the Board has been interfering too much with the sacred right of the people to be *humbugged*; and with the equally inalienable right of medical impostors to obtain money under false pretenses. While we think the Illinois State Board of Health might have done more to educate the people of the State in sanitary matters by adopting some of the methods practiced successfully by the Michigan State Board, and that some of the provisions of the law could be greatly improved by judicious amendments, we can find no apology for the present line of opposition developed in one branch of the Legislature. If a State law for regulating medical practice and protecting the public health is defective, amend it. If the law is useless, repeal it. If the Board appointed to execute the law is inefficient, reorganize it. But do not adopt the disreputable method of starvation by withholding supplies.

EDITORIAL NOTES.

DEATH OF M. CHEVREUL, the oldest, and one of the most eminent chemists of France, at the age of 103 years. A press despatch, dated Paris, April, 9, 1889, makes the following announcement:

"M. Michel Eugene Chevreul, the distinguished

French chemist, is dead. He was born in Angiers Aug. 1, 1786. Having completed his studies in the Central school of that place, at the age of 19 he went to Paris, where he was engaged in the chemical factory of the celebrated Vauquelin, who discovered in his young pupil such aptitude and sagacity that he intrusted the direction of his laboratory to him. In 1810 he was preparator of the chemical course in the Museum of Natural History, and in 1813 was appointed professor in the Lycee Charlemagne, and officer of the university. In 1824 he was made director of the dyeries and professor of special chemistry in the carpet manufactory of the Gobelins, where he had leisure to follow his favorite pursuits into detail, one of which was his investigation of animal oils, or grease. In 1823 M. Chevreul published a work on this subject, for which the Society for the Encouragement of National Industry awarded him the prize of 12,000 francs. M. Chevreul has written various scientific works, some of which have been translated into various European languages. M. Chevreul had contributed to the proceedings of scientific societies, to dictionaries, and to other works. In 1830 M. Chevreul succeeded his former master, Vauquelin, in the Chair of Chemistry at the Museum of Natural History, since which time he has become Fellow of the Royal Society of London and President of the Society of Agriculture. In 1864 he was appointed director of the Museum of Natural History for five years, and in 1869 reappointed for another quinquennial period. He was made Commander of the Legion of Honor Sept. 24, 1849."

DR. EDWARD T. BRUEN, Assistant Professor of Physical Diagnosis in the University of Pennsylvania, died of pneumonia, March 31, 1889, at the early age of 39 years. He was the author of a creditable work on the "Physical Diagnosis of the Heart and Lungs," and visiting physician to the Philadelphia and German Hospitals.

A PROBLEM IN MATHEMATICS.—If all the sources of water supply to the chain of great lakes to which lake Michigan belongs remain the same, and the present avenues of exit the same, while a new channel is cut from the lake just named southward, permitting the constant discharge of 500,000 cubic feet of water per minute, how long would it take to lower the water level in the lakes three feet, and to what extent would

such change in the lake level diminish the rate of discharge through the artificial channel?

THE MEDICO-CHIRURGICAL FACULTY OF THE STATE OF MARYLAND will hold its next annual meeting in Baltimore, Md., commencing on Tuesday, April 23, 1889, and continue three days. The Annual Address is to be delivered by Prof. Wm. Osler, of the Johns Hopkins University, on the "License to Practice with reference to State Examining Boards."

SOCIETY PROCEEDINGS.

Philadelphia County Medical Society.

Stated Meeting, January 23, 1889.

THE PRESIDENT, W. W. KEEN, M.D., IN
THE CHAIR.

(Concluded from page 532.)

DR. EUGENE P. BERNARDY read a paper on
BINIODIDE OF MERCURY. ITS ANTISEPTIC USE.
OBSTETRICAL CASES.

Case 1.—Mrs. L., æt. 19, first pregnancy; was called to attend her (January 24, 1886) in a premature labor; she was pregnant about six and a half months; when I arrived, I found she had been delivered of a dead male child; the placenta came away in two hours; the patient did well up to the evening of January 27, when she was taken with a chill, which was repeated in three hours; when I saw her on the morning of the 28th, her skin was hot and dry, face flushed, pulse 112, temperature 102°; tongue thickly furred, abdomen slightly swollen and very sensitive; lochia offensive. Ordered quinae sulph., gr. xx.; morphine sulph., gr. ¼ night and morning; poultice over abdomen, and hot vaginal injections of 1 to 4,000 solution of the biniodide of mercury every four hours; at the second injection the discharges became free from any odor. January 29, pulse 100, temperature normal. This treatment was kept up, with the exception of the large doses of quinine, to October 5, when the injections were reduced to one a day for about four days, when the patient was discharged cured.

I have confined this case since of a full-term, living child; the biniodide injections were used at once; she had a good lying-in; discharged on the ninth day, well. (The above case really belongs to my second series, but the manuscript was mislaid at the time, and found too late to be incorporated in my second paper.)

Case 2.—Mrs. M., æt. 35; fifth confinement;

during her pregnancy she had worked very hard, doing almost the work of a man. Was called to attend her in labor, March 18, 1886; when I arrived at her bedside I found she had been in labor since the previous day; she appeared completely worn out, having hardly any strength to bear down; the family refused positively instrumental interference. I gave two doses of the fluid extract of ergot, teaspoonful, repeated in half an hour; under its influence the child was born; the placenta soon followed.

The patient did well up to March 24, when, in the evening, she had a severe chill, which again occurred the following morning (March 25). I saw the patient on the following day; She seemed to have aged fully ten years; her face was drawn, and of a deep yellow color, eyes bright and sparkling with delirium; pulse 140, temperature 105°; the abdomen was immensely swollen, and could not bear to be touched, more especially on the right side. Diagnosed metro-peritonitis. Lochia arrested. Ordered quiniæ sulphatis, gr. xx, night and morning; morphia sulphatis, gr. ʒi, whenever pain was severe; hot poultice over the abdomen, hot vaginal injections of 1 to 4,000 solution of biniodide of mercury. March 28, pulse 120, temperature 101°; lochia returning, abdomen not so sensitive. This treatment was continued up to March 31; the abdomen now allowed of closer examination; in the right inguinal region could be detected a large mass; vaginal examination showed the uterus bound down and completely surrounded by lymph. Dr. W. Goodell, being called in consultation, verified the diagnosis. The biniodide injections to be continued; internally, quinine sulph., gr. iij three times a day, besides an alterative tonic. The patient gradually recovered her health, without any additional treatment.

In this case the injections of the biniodide were constantly used for over a space of three weeks, first every four hours, then three times a day, then once a day, without the slightest systemic action of the drug occurring.

Case 3.—On July 11, 1886, I was asked to see Mrs. W., in consultation with her family physician; on entering the house a most sickening odor struck my nostrils; it reminded me of uterine cancer in its last stage; the more I advanced, the worse the odor became; at last I reached the room and bedside of the patient; of all odors I never want to smell the like again; as the nurse remarked, it was worse than decayed carrion; how the patient lived through such a condition was simply miraculous.

I found she had aborted about two weeks previously, and had declined any interference in regard to extracting the placenta, saying, "it will come away." On examination, I found the vagina full of sticky, horribly-smelling, broken-down placental tissue, the mouth of the uterus opened,

the uterus full of the same kind of material as found in the vagina; the patient declined the use of any instruments, so I broke down and pulled out all that came within reach of my finger; I then washed out the uterus with a hot 1 to 4,000 solution of the biniodide of mercury; not yet satisfied, I washed out the parts with another quart of the solution (1 to 4,000, until the water came back clear.

I did not see the case again, and, in answer to a letter to the attendant physician, I received the following:

"Philadelphia, May 20, 1887.

"*My Dear Doctor:* I am glad to inform you that Mrs. W. did very well. The *iodide of mercury pellets* acted like a charm. There was no unpleasant odor attached to the discharges after we began their employment. . . . I have been an ardent advocate of potassium permanganate, but I am now a convert to the biniodide as an antiseptic."

Case 4.—Mrs. H., primipara, æt. 30, fell in labor November 18, 1886. On my arrival at her bedside I found she had been in labor for some time, the mouth of the uterus wide open, bag of waters unruptured, vertex presentation. On making abdominal palpation, detected at once a twin pregnancy. After a somewhat lingering labor the first child (boy) was born. On examination, I found the second child (girl) presenting with vertex left posterior. The head came down very slowly, and, on the solicitations of the patient and family, the labor was terminated with forceps. The patient did well up to the evening of the second day, when, about midnight, she was taken with severe frontal headache and chills. I saw the patient in the chill; half an hour after her temperature was 104°, pulse 140; delirious. Ordered quinine sulphat., gr. xx, at once, and repeat next morning. Next day (November 21), temperature and pulse the same, completely out of her mind; lochia almost ceased flowing, and what was present was offensive; abdomen extremely sensitive to the touch. Ordered the quinine to be continued, gtts. x tr. digitalis four times a day, hot flaxseed-meal poultices over abdomen, hot injections in the vagina of 1 to 4,000 biniodide of mercury every four hours. The following day the lochia returned normal. The condition of things remained about the same up to November 25, when the symptoms were improved. The patient was discharged well December 4, 1886.

(The following case is the first patient on whom I used the biniodide of mercury injections, and whose history is given in my first paper, June 4, 1885.)

Case 5.—Mrs. D., third confinement (being compelled to leave the city, she fell into the hands of another physician), fell in labor September 6, 1886. After a lingering labor she was delivered

of a stillborn child. On the second day, as far as I can learn, all the symptoms of an attack of puerperal fever set in; she remained very sick for several days. No vaginal injections of any kind were used. When I saw the patient, on September 19, 1886, she was suffering with an extremely tender abdomen, more especially on the right side, on which side could be detected a small lump. Vaginal examination disclosed the uterus partially surrounded by lymph. Discharges from the vagina very offensive. Pulse 100, temperature 101° – 102° . Nothing could be retained on the stomach; as a drink, frozen champagne was ordered. Quinine sulphate, gr. x, once a day; equal parts of ungt. hydrarg. and belladonna to be rubbed over the abdomen once a day, followed by hot poultices, hot injections of the 1 to 4,000 biniodide three times a day. My following visit found my patient improved, and in a week was discharged, but it was some time before she regained her usual strength.

On November 1, 1887, I delivered the above patient, after an easy labor, of a large female child. Immediately after the placenta came away I washed the uterus out with a 1 to 4,000 injection of the biniodide. The injections were ordered to be used three times a day throughout the lying-in, which was perfectly normal, and the patient discharged, well and strong, on the ninth day.

Case 6.—Mrs. C., æt. 19; first pregnancy; was called to attend her on the morning of August 19, 1888. After an easy labor she was delivered in the afternoon of a large male child; the placenta came away in about twenty minutes. The following day the patient was doing well, but had not been washed, and the odor in the room was very disagreeable. On my following visit I found the patient in a high fever, temperature 103° , pulse 130, full and quick; tongue dry and chippy. The skin from the posterior part of the vulva back to beyond the anus was raw and covered with minute bloody points; abdomen very tender; lochia, what there was, extremely offensive.

On close inquiry I found that the mother of the patient, who was supposed to be nurse, had gone on a drunken debauch since the birth of the child, no doubt celebrating her "grandmotherhood." The patient was placed at once in charge of a competent nurse; hot poultices were ordered to the abdomen; quinine sulph., gr. v, morphia sulph., gr. $\frac{1}{4}$, every four hours; hot injections in the vagina of 1 to 4,000 biniodide of mercury every three or four hours. Equal parts of zinc ointment and Goulard's cerate were applied over the raw surface.

August 24, pulse 110, temperature 101° ; lochia coming freely and without odor. August 26, pulse 100, temperature 99° ; 4 P.M., pulse 100, temperature 101° . Condition better, treatment continued; patient discharged, entirely cured, September 1, 1888.

With the three cases reported in my first paper, eight in my second, and the six cases just detailed, in all, seventeen (obstetrical) cases in which the biniodide of mercury had been employed, gives us, certainly, sufficient data to draw positive conclusions.

ABDOMINAL ABSCESS INTERCURRENT WITH TYPHOID FEVER.

Case.—On April 20, 1887, I was requested to see Mary B., aged 5 years. The little patient had been ailing for the past week, suffering from constant frontal headache, very feverish, loss of appetite, and having a diarrhœa. I found her in bed, with a temperature of 103° , very quick, compressible pulse, tongue dry, and a number of rose-colored spots over the abdomen and chest. The case was running the ordinary course of typhoid fever, when, on May 5th, the child was taken with a sudden, sharp pain in the right iliac region; my visit found the child suffering agonizing pain in the abdomen, which was tense and swollen; in the right iliac region could be felt a lump the size of an egg; under appropriate treatment the acute pain somewhat subsided. On May 8th my attention was called to the navel, which had become red, inflamed and pouting; on touch a feeling of fluctuation was imparted to the finger. May 10th, the child passed from the bowels a large quantity of pus; the angry appearance of the navel disappeared, all acute symptoms seemed abated. On my visit of May 12th I found the navel again inflamed, with positive indications of pus underneath; the following day it broke, discharging about a cupful of pus. I now suggested a consultation in regard to the advisability of an operation. It was declined. Same condition continued up to the first of June; the child by this time had become greatly emaciated, constant discharge of pus from the navel, and symptoms of septic poison were commencing to show themselves. At last, on June 12th, consent was given to an operation. June 13th, Drs. Allis, F. Elder and C. Reed were present. The patient was etherized by Dr. Reed, after a close examination, and taking the weakened condition of the child into consideration, and also that the abscess cavity having made an opening at the navel, it was decided that, instead of opening the abdominal cavity, a counter-opening in the left iliac region be made and a drainage-tube extending from the navel to it be introduced, and the abscess cavity washed out. I washed out the abscess cavity through the tube with a two-quart solution of 1 to 4,000 biniodide of mercury; the abdomen was then covered first with biniodide gauze, over which was laid a layer of biniodide wool, all held in position by a bandage that had been washed in a 1 to 4,000 solution of the biniodide of mercury. The abscess cavity was ordered to be washed out morning and night with a 1 to 8,000 solution of the biniodide; the child

rallied well from the effects of the ether. While washing out the cavity, on May 17th, a piece of straw came through the drainage-tube. May 22d, discharge of feces through the lower end of the tube; which occurred two days in succession; for the following ten days, when the child partook of food, more especially if this was an egg, within a half hour some of it partially digested would appear at the end of the upper part of the tube; if the discharge occurred later than a half-hour it would appear at the lower end of the tube; this clearly demonstrated a fecal fistula in connection with the abscess cavity. Gradually all discharges ceased; and the tube was taken out July 23, 1887; a week later both openings were closed, but it was several months before the child could resume her ordinary diet; apples would inevitably bring on severe colic.

None of us at the time of the operation went further than to "hope" that the little patient would get well. The case demonstrates well the antiseptic properties of the biniodide. It was an extremely warm month, and, with the exception of the two or three days on which the feces passed down through the tube, the odor of the discharges was held in abeyance.

Double Laceration of the Cervix.

Case.—Mrs. F. had a large, double laceration of the cervix following a natural labor. I first saw the case in May, 1885, and advised operation. Operated October 5, 1885. Extensive denudation had to be made; fourteen silver stitches were necessary; hot water was used to cleanse the parts during the operation. On the second day a very offensive bloody discharge occurred. The vagina was washed out with a hot 1 to 4,000 solution of the biniodide of mercury three times a day; at the first injection all odor disappeared, and did not return throughout the rest of the treatment; the stitches were taken out on the tenth day, with perfect union.

Abscess of Right Foot.

Case.—In February, 1887, I was called to see Master McG. About a week previous a heavy box fell on his foot; painful at the time, but not painful enough for him to give up his work, he continued to work up to February 10, 1887; on the previous evening his foot became swollen and painful; under poultices the inflammation centred, and on February 20, the abscess broke. The opening was stubborn to heal; offensive pus was discharged; every day I injected the cavity with a 1 to 2,000 solution of the bichloride of mercury and packed; this treatment was kept up for ten days without any change; the bichloride was then changed to a 1 to 4,000 solution of the biniodide of mercury, the discharges were made pure, and in the course of another ten days the opening closed, but the foot remained tender for several weeks.

Abscess Extending from the Right Axilla down the Right Side to One Inch below the Floating Rib.

Case.—W. S., æt. 30, barber, of scrofulous habit, somewhat dissipated, having a wart on the right middle finger, picked it with his fingernails; the result was an acute inflammation of the entire arm. I saw the case July 16, 1888; under cooling applications, the inflammation soon abated. About July 21, 1888, the right side, extending from the axilla down to midway between the last rib and the crest of the ilium became intensely inflamed; the pain was excruciating, and large doses of sulphate of morphia gave only momentary relief; large flaxseed poultices liberally sprinkled with laudanum were applied. On the 24th I detected fluctuation at the lower border, made an exploratory incision, and obtained half a cupful of fetid pus and broken-down blood; this gave slight relief. On the 26th the pain returned tenfold; the same evening, the patient having been etherized by Dr. S. Solis-Cohen, I enlarged the previously made incision to three inches, and about half a pint of extremely fetid pus was discharged; the finger was then introduced, and two encysted pus sacs, situated at the edge of the scapula, were ruptured, and another half pint of pus was discharged; the cavity was then washed out with a 1 to 4,000 solution of the biniodide of mercury, a drainage tube introduced, flaxseed poultice applied, and over all a layer of biniodide wool.

Next day I found the patient had had a good night's rest; I removed the poultice; cavity to be washed out three times a day with the biniodide; drainage tube taken out on the fourth day, and within a week the case was discharged well. It is hardly necessary to state that good nourishment, iron, and quinine were ordered. After using the biniodide no odor was perceptible in the discharges.

Three Cases of Carbuncle.

Case 1.—April 23, 1887, I was asked to see Mrs. P., æt. 72, and found her suffering with a carbuncle on the back of the neck, six inches long and four inches wide. It was riddled with a number of suppurating points; on the previous day the patient had been given up by her medical attendant as incurable. On Sunday, April 24, 1887, after the patient had been etherized, the wound, instruments, and sponges were made antiseptic by being washed with a 1 to 4,000 solution of the biniodide, after which a crucial incision was made and all the hardened tissue dissected out, down to healthy tissue, thoroughly washed out with the biniodide, and a flaxseed meal and charcoal poultice applied; the sore to be well washed three times a day with the biniodide, when a fresh poultice was applied. Internal treatment, quinine, and full diet. In

twenty days the patient was discharged well. The disagreeable odor in this case was not entirely dissipated, but was held under control.

Case 2.—Mr. B., coal merchant, aged 40. Carbuncle in right shoulder, size of an egg, hard, indurated, extremely painful to the touch, and a point of suppuration at the centre; the case was seen April 7, 1888. The next day, after the patient had been etherized, I made a deep, crucial incision, and dissected out all the hard, indurated tissue; the same treatment was used as in Case 1. No odor connected with the discharges. Patient discharged, cured, in two weeks.

On October 20, 1888, I was again asked to see the above patient. I found him suffering from an attack of herpes of the back of the neck, which was, in a few days, followed by a number of abscesses, two of them resembling small carbuncles. A charcoal poultice was applied, and in three days all the abscesses were opened, but during the following week there seemed to be no change for the better. I then ordered a piece of linen to be saturated with a 1 to 4,000 solution of the biniodide and applied to the surface, and over this a flaxseed-charcoal poultice; within 48 hours the angry appearance of the abscesses and skin abated, and in four to five days more all inflammation had disappeared, when the patient was discharged.

Case 3.—J. E., aged 69, was taken sick about three weeks previous to my seeing him. It first commenced with a painful tumor on the neck. When I saw the case (July 19, 1888), the entire surface from the superior curved line of the occipital bone down to the seventh cervical vertebra and from ear to ear was one immense, suppurating surface, covered with a thick, yellowish green membrane. The discharges were highly offensive. Pulse quick and compressible; slightly delirious; tongue covered with a thick, black, highly offensive membrane. Ordered a piece of linen to be saturated with a 1 to 4,000 solution of the biniodide and applied over the surface, and over this a charcoal-flaxseed poultice every three hours. The odor was held in abeyance. This treatment was continued for about ten days, when the surface became clear of all adventitious membrane. Poultice was continued; carbolic acid was ordered in place of the biniodide. Patient discharged, cured, September 20, 1888.

Dr. S. Solis-Cohen saw the case for me in August, and we concurred in one prognosis, which was death; but we were more than agreeably surprised.

BINIODIDE OF MERCURY WOOL AS AN APPLICATION OVER THE CHEST IN PULMONARY TROUBLE.

When, in the winter of 1886, I first ordered the chest of a child suffering with catarrhal pneumonia to be enveloped in a layer of the biniodide of mercury wool, it was simply to overcome the dis-

agreeable matting of the cotton. The child, previously to its use, was very restless, and seemed to suffer pain. On the following visit I found that the little patient had had its first quiet sleep since the commencement of its sickness; since then I have almost entirely discarded the use of cotton. The results in a number of cases lead me to believe that there must be something more than the warmth of the wool. Can it be that the heat of the body disengages the biniodide, and as the consequent result, the patient is constantly surrounded by an antiseptic atmosphere?

In a case operated upon for cancerous constriction of the bowel, by Dr. Charles B. Penrose, the patient, about the fourth week, was seized with a sharp pain in the right side below the nipple. Counter-irritants did not relieve her. On auscultation, crepitant râles were easily detected in the lower right portion of the lung, under the point where the pain was complained of. The side was enveloped in biniodide wool, and within twelve hours the pain had entirely disappeared. In the neuralgic pains always present in a case of phthisis I have found the wool to invariably diminish, if not entirely dissipate the pains, and the expectation seems easier and in smaller quantities.

My attention was called to the following by my office pupil, J. N. England: "Biniodide of Mercury Pulverization for Tuberculosis" (*American Journal of Pharmacy*, October, 1888). Miquel and Rueff's formula is given by the *Arch. de Phar.*, September 5, 1888, as follows: Biniodide of mercury and iodide of potassium, of each 1 gram; distilled water, 1,000 grams. The solution is stable. At the beginning 10 c.c.m. are sprayed once daily, to be increased to 25 c.c.m. twice daily. The larger portion of the liquid should be inspired. It reaches the lungs, says the author, but salivation does not follow, even after months of treatment. The sputa changes in character and diminishes in quantity; the number of microbes is lessened, but these organisms rarely disappear completely. The cough increases at first, and afterward subsides.

If my theory of the disengagement, by heat, of the biniodide from the wool be correct, its action will readily be explained by the above experiments of Miquel and Rueff.

DISINFECTANT IN THE ALVINE DISCHARGES OF TYPHOID FEVER.

For the past two years I have used the pellets of the biniodide dissolved in the alvine discharges of typhoid fever, and the results have always been satisfactory.

In the spring of 1886 I treated an extremely bad case of typhoid fever. The patient was broken down from dissipation, having had, about two weeks prior to his illness, an attack of delirium tremens. The alvine discharges numbered from twenty to thirty a day, and were highly offensive;

chloride of lime and different forms of chloride and sulphate of iron were used without any diminution of the sickening odor. I then ordered two (1 to 4,000) pellets of the biniodide of mercury to be dissolved in $\frac{1}{2}$ pint of water and placed in the bed-pan, to be renewed every time the pan had been used by the patient. The odor was completely dissipated, and kept so.

In another case the bichloride of mercury pellets were used without success; the biniodide pellets gave the desired result. In a case of labor which, at the end of the lying-in, terminated in an attack of typhoid fever, the nurse used the biniodide pellets on her own account in the bed-pan; there was no disagreeable odor throughout the course of the disease.

The description of the action of new medicinal preparations or new properties to an old medicine necessitates tedious histories of cases; this must be my excuse for dragging through such dry details.

It is not my intention to present to you the biniodide of mercury as the one and only infallible antiseptic; I simply present my results, and have tried to give impartial histories, without exaggeration, simply as they have occurred. But the action and results of the biniodide of mercury fully strengthen my belief in its stronger antiseptic value and non-irritating properties over the bichloride.

221 South Seventeenth St.

DR. FRANK WOODBURY: Since Dr. Bernardy read his previous communication on the use of this agent in obstetrics, I have resorted to it in several cases where symptoms of septicæmia appeared, and where the lochia were offensive. In one case of placenta prævia, where there were offensive discharges, and there was danger of premature labor, I found that the use of this agent in the strength of 1:4,000, corrected the fetor, and the patient escaped premature labor. I subsequently lost sight of her, but I suppose that delivery has since taken place.

I have two criticisms to make in regard to these so-called pellets of biniodide of mercury.

In the first place, they are not pellets, and, in the second place, they do not contain the biniodide of mercury. They are really troches, and their appearance is so inviting that they might be taken by children, or persons not familiar with their dangerous properties, as confectionery. I think that if they were really pellets, or if they were formed in the shape of bacilli, divided into ten portions, so that by breaking off one portion the proper amount of the agent would be secured, the danger would be lessened.

In reference to the second criticism. The biniodide of mercury is not soluble in water. It is soluble in an excess of bichloride of mercury, or in an excess of the iodide of potassium. The

preparation is really and iodo-hydrargyrate of potassium. This is really Neisser's reagent, which has been used as an excessively sensitive agent for the detection of alkaloids, and for the recognition of ammonia and compound ammonias.

I have one thought to offer, which seems suggestive: The value of Neisser's reagent consists in its power to precipitate alkaloids, and to decompose compound ammonias. Now in these cases of bacilli found in offensive lochia and suppurating cavities, the bacilli are probably accompanied by the products of their growth and multiplication. These resemble ptomaines, and are, properly called leucomaines. Philips, of Edinburgh, found that by injecting into animals a watery extract obtained from the sputa of consumptives, and from other tubercular products, he produced the ordinary symptoms of phthisis, fever, emaciation, loss of appetite, and strength, and progressive decline of the powers of life, and finally death. Now, it is probable that these substances, which are alkaloidal in character, are precipitated by Neisser's reagent.

We cannot at this time enter into the question why certain agents are antiseptic and others are not, or why one should be more antiseptic than another. This is a matter of experiment. We do know, however, that Neisser's reagent has for a long time been used in the laboratory for the precipitation of alkaloids, and this fact interested me in this connection as possibly offering an explanation of the effect of this agent in the treatment of suppurating wounds and of offensive lochia.

DR. E. P. BERNARDY: From the start I objected to the shape of the pellets, thinking that they looked too much like candy, and I think that there will soon be a change, so that this danger will be avoided. The pellets of bichloride look very much like chlorate of potassium lozenges, with the exception that the word "poison" is stamped on them.

In regard to this being a double salt. This was the first thing that struck my attention. When I first used this preparation in 1884, I dissolved the biniodide in alcohol. This was found to be inconvenient, and through the kindness of Mr. Hayes, who allowed me the use of his laboratory, his assistant and I worked up this subject. We added iodide of potassium, and then found that the slightest moisture imparted to one pellet was enough to destroy the entire bottleful. We then decided to add the muriate of ammonium, which prevents this chemical reaction until the pellet is thrown into water. The pellet goes in as the biniodide of mercury, and the iodide dissolves it, but before the change takes place it has been used upon the patient.

In regard to my use of this preparation. I have studied it faithfully, and have tried to look upon the cases in an unbiassed way, and to give

a fair history of them. I have sometimes first used the bichloride, and it has not fulfilled the intention as the biniodide has done.

DR. JOSEPH PRICE presented an

EXCEPTIONALLY LARGE OVARIAN ABSCESS.

A few years ago this specimen would perhaps have been considered unique. Only a short time ago abscess of the ovary and very large pus tubes were looked on with considerable doubt. This was particularly true of abscess of the ovary. Some operators now could, perhaps, put on record more cases of ovarian abscess than could be found in all the old records. This was an enormous abscess of the ovary, probably as large as a child's head, and filled the pelvis completely. The condition of affairs was such that would a few years ago have been described as a pelvis filled with mortar, and where we were satisfied that there was simply rigidity of the vaginal vault.

I saw the patient from whom this was removed for the first time last evening. The diagnosis made by the physician was pelvic abscess or a large collection of pus in the left ovary or tube. There was but little doubt in my mind as to the correctness of the diagnosis. The pulse was 140, the temperature 103° . I decided to operate this morning. It would have been better to have operated last night if I had been prepared. The abscess extended above the pelvic inlet. There were adhesions to all the viscera, to the omentum, and to the small and large bowel from the vermiform appendix to the sigmoid flexure.

I present this simply as a specimen of exceptionally large ovarian abscess. This is the second case that I have had within a few days. The first one was not quite so large. The tube in this case was large and tortuous, and had a sausage like feel.

There is one point of interest, and that is, with reference to the character of the fluid that we sometimes find in the pelvis—for instance, in the tubes. If fluid presenting the same characters were emptied from any other portion of the body, as from the brain, axilla, or popliteal space, nothing would be said about the character of the fluid; it would be regarded as pus.

Massachusetts Medical Society,

SECTION FOR CLINICAL MEDICINE, PATHOLOGY
AND HYGIENE

ALBERT N. BLODGETT, M.D., SECRETARY.

Stated Meeting December 12, 1888.

Dr. John A. Jeffries presented a short article

entitled *A Good Bread for Diabetics, containing Less than Five per cent. of Starch.*

DR. E. W. CUSHING read a paper on

THE PATHOLOGY AND DIAGNOSIS OF SO-CALLED
PELVIC CELLULITIS, WITH SPECIMENS OF
PYOSALPINX.

(See page 551.)

DR. SINCLAIR: I do not belong to the surgical section of those who treat disease of this kind. I have never operated, and consequently can say nothing at all in that direction. I have more or less acquaintance with the medical aspect of so-called pelvic cellulitis or peritonitis from the time when I was a student of Dr. Simpson, of Edinburgh, who first opened my eyes to this disorder, and I became deeply interested in it from the first. I think I was the first to describe a case of pelvic cellulitis as such in this city or State. The discussion on that occasion was very interesting. The late Dr. Jackson rather doubted the possibility of there being a sufficient amount of cellular tissue about the junction of the neck and body of the womb with the broad ligament to have allowed such an amount of infiltration as was described in that case. Suffice it to say that we regarded it as abscess of the broad ligament. It was within ten days after confinement and followed within about three weeks by a discharge of pus through the rectum. I think it was 28 years ago. Since that time I have studied it as far as I could both from touch and observation, but I have never had an opportunity of seeing the post-mortem examination of such a case except in one instance. Probably twenty cases or more came under my observation as physician of the City Hospital, but this one showed most clearly what had already been written and published by Bernutz in his famous work on pelvic peritonitis and uterine diseases. That case was one of tubercular disease of the fallopian tube, and there were also, I think, some tubercles deposited in the interior of the uterus. At that time I became a convert to the Bernutz and Goupil theory, which was entirely contrary to the one received from Prof. Simpson. It seemed a revelation—like being born again—to accept the theory that this condition of things was intra-peritoneal.

In the Boston City Hospital Reports, vol. i, there is a record of some twenty-one cases of pelvic cellulitis, or "peri-uterine inflammation," inasmuch as I think that term would cover the ground in these obscure cases better than "pelvic cellulitis." The history and the termination would conform much to those cases read by Prof. Rosenwasser. I have no doubt that the conclusion now reached by gentlemen at home and abroad—surgeons and laparotomists, that the best treatment of a large number of these cases has been discovered in the removal of the diseased organs, which are generally the ovary or fallopian

tubes—is the correct one. There are certain cases, however, of true *pelvic cellulitis*, but those generally follow confinement and are septic in their nature.

We have a mild form of pelvic peritonitis frequently met with in girls—recurrences of sharp pain; they are “laid up” for a day or two, and these recur and keep recurring, but very little attention is paid to them; still they may mean a great deal.

The subject is intensely broad. I do not know of another in the whole domain of gynecology that is wider and more interesting; and, as I said in an introductory note in my paper in the Hospital Reports, I believe that 50 per cent. of the disorders of women which we come in contact with are due to some kind of peritonitis, some localized pelvic peritonic trouble. I know that at the time I was laughed at for such an assertion, but I think, instead of 50 per cent., I should set it higher to-day.

DR. S. C. WHITTIER, President of the New Hampshire State Medical Society, said: I have been very greatly pleased with Dr. Cushing's paper and the explanation of the cases that he has given us. But one thing which I think should impress our minds more than perhaps almost any other, is the getting away from, or losing sight of, the idea of pelvic cellulitis. I have come pretty thoroughly to the belief that we really get salpingitis instead; and I now should never examine a typical case of what we call “pelvic cellulitis” without expecting to find salpingitis, and I don't think I should probably be mistaken.

I have had quite an extensive opportunity, under the guidance of Dr. Cushing, of examining almost all of the patients from whom these specimens were removed, and have seen a great many of his operations, and I certainly have been very highly edified and instructed.

DR. JOHN HOMANS: I am much interested in this very large display of specimens of diseased tubes; it brings the fact to the front again that we owe this to Mr. Tait that he first called our attention to this condition of things.

A few weeks ago I had a case much like some of these. The woman had been for seven years an invalid. She was the wife of a railroad engineer unable to employ a servant. She was not able to do much, and had been a good many months in the hospitals. Life was not a burden to her, but still hardly worth living without being able to do anything. On examination, I found in the left iliac region a bunch about as large as a pear, and at the operation I had to go through the mesentery to make an opening into the sac, which I finally, after considerable difficulty, removed. It was the left ovary and tube. She had a drainage-tube inserted, and did very well. The other day, several months after the operation, she called to see me. She was able to work and enjoy herself.

It seems to me that the treatment by laparotomy is the right one. The disease has been going on for some time in many cases, and it is pretty hard to keep a person waiting who is unable to do anything.

Another case I operated on with considerable hesitation, because it was my first operation. It was one of those abscesses connected with the rectum, and I feared I should have a faecal fistula. The uterus was displaced to the right and fixed, and when the abdomen was opened I found a tumor bulging out on the left side beneath the broad ligament, beneath the peritoneum, and with the the intestines above it. I aspirated, enlarged the opening, putting in a glass drainage-tube. The woman was better for the time being, but whether it was a permanent cure I do not know. No faecal fistula followed.

Of course all these improvements come from the enlarged practice in ovariectomy. As the operation was introduced by Sir Spencer Wells, and the familiarity of the abdomen obtained by ovariectomists, gradually surgeons became more confident, until a person of Mr. Tait's temperament and courage and decision came along and discovered this condition of the tubes and ovaries.

I think Dr. Cushing is to be congratulated on the results of his efforts; it is a remarkable series of cases and a remarkable showing.

DR. R. H. FITZ: The question that first occurs to me is this: what happens to these cases if not operated upon? Until the removal of acutely diseased tubes the patient was let alone and went under medical treatment; that has already been referred to. When the first of these tubes was brought to me it was a surprise to me that in making post-mortem examinations it was a rare thing for any such condition to be seen; the inference being that if no operation was performed the fluid was gradually absorbed, the pus became absorbed, the tubes thickened, and one had in the person who got beyond the climacteric simply adhesions and thickened tubes. The amount of suffering which these women may have undergone while this process was being brought about was something that I had no idea of at the time; and it seems to me this is the natural history of this class of cases; if the attacks are not so violent as to indicate a spreading peritonitis and demand immediate operation for the relief of that condition, they will generally, the majority of them, dry up and adherent masses will remain, which evidently will give rise to very little disturbance. But it is very evident from the experience of Dr. Cushing, and familiar to other operators, that a great deal of suffering does arise until that thing in the history of the process is brought about; and that the results of these operations are very striking in relieving, as far as the present evidence goes, these serious disturbances.

With regard to the more immediate subject before us—the relation between these pelvic abscesses and tubal inflammation and cellulitis, so called—there is no question that a pelvic cellulitis does occur, and that it results in the formation of pus, but that it gives rise to any considerable tumors limited to the subperitoneal connective tissue seems to me not very likely. The course of pelvic inflammation is either forwards or backwards, and one has a long suppurating track insisted of sharply defined circumscribed tumors that are represented by the tubal inflammations, and also by the cases of circumscribed peritonitis, which are so generally of tubal origin.

I quite agree with Dr. Cushing that the great majority of these cases are not cases of abscess in the pelvic connective tissue, but are cases either of dilated inflamed tubes or of circumscribed peritonitis.

DR. J. P. REYNOLDS: That is a point which I wish to bring up a little. I don't differ perhaps at all from the statement of the general fact, that a vast number of cases which have been considered to be the result of inflammatory process in the peritoneum, are really cases of these inflamed organs, or of the tube, containing confined serum or pus. To that statement no criticism can be made; but I should not want to believe that anybody has seriously asserted that such collections of pus in occluded tubes were the result of inflamed areolar tissue. Septic inflammation in the lying-in-period, for instance, ordinarily follows the track of the subareolar tissue, that is, where the investing membrane lies loosely attached to the uterus, but in the two lateral borders is a frequent seat of such inflammatory processes, less frequently on the anterior and posterior surfaces, because there the investing peritoneal membrane is extremely closely attached to the uterus. It is an old matter of anatomical statement that the areolar tissue extends over the peritoneum, over all the viscera, and inflammatory processes occurring in it are only very exceptionally limited and converted into circumscribed disease; but that ordinarily all the various degrees of inflammation, sometimes extending over a very large portion of the abdominal surface occur, seems to me to be a fact not at all conflicting with the statement that a great many cases have been mistaken for inflammation of that tissue, and perhaps involving the peritoneum over it, when really they were inflammations, as I understand the writer of the paper to urge, of the subjacent organs and of their interior lining, resulting in the formation of masses of liquid. I don't say that it is necessary to imagine that old pathologists were so much in error when they stated that inflammation inside the Fallopian tube was the result of inflammation of the areolar tissue over it; but that there is such tissue capable of doing vast mischief, and does constantly in

the lying-in period, seems to me to be a fact we must still admit. I don't think that it conflicts at all with the statement which underlies the history of these cases, that in the great majority of cases it is an internal inflammation occluding the tubes and resulting in hydrosalpinx or pyosalpinx.

DR. F. L. BURT: In many cases belonging to this class the diagnosis is of considerable importance, although in some cases it may not be really so necessary, because if we are certain that an operation must be performed, we are equally certain of being able to clear up the whole matter at that time. As a point by way of an aid to diagnosis, I would say a few words which might be of interest in regard to the use of electricity in these cases. The benefit to be derived from this agent will depend upon whether there is or is not pus present as a result of the pelvic inflammation; that is, whether an abscess or not.

To illustrate this I will briefly relate the facts concerning two typical cases. A woman of 45 years desired to enter the hospital, but I could not admit her, as there seemed to be no operation indicated, yet she was sadly in need of treatment, as she was a complete wreck. Examination showed the results of an old pelvic inflammation, and the outline of the uterus could not be made out at all. The condition was one which would most usually be diagnosed as fibroid, but there was no such tumor. I offered to treat the case at my office as a free patient. One application caused such an amount of absorption that I could easily outline the uterus after it, and with six applications there was such relief that she was able to resume work. The second case was diagnosed as fibroid which had considerable pain and flowing associated. The removal of ovaries and tubes was considered. As a preliminary treatment I applied galvanism, positive intra-uterine. The result was to increase the pain and not to stop the hæmorrhage in the least.

Previous experience led me to doubt the diagnosis, and the operation revealed a double pyosalpinx. A private case of which I show the specimen well illustrates this latter type. A lady of 50 years had suffered during the past six years all the tortures resulting from a pelvic inflammation. There was treatment at the beginning for pelvic inflammation, and what was called a cure resulted. Quite recently she was told that she suffered simply from nervousness. She was referred to me by Dr. Manuel for treatment. I found it to be a typical case of pelvic inflammation, and the pelvic organs were joined in one solid mass, but the existence of pus was uncertain.

I began with galvanism, but it did not help in any way, and the pains grew worse. The reason you will see, for a little later I did a laparotomy, and the result was the removal of the double pus tubes which I show you. The case has recovered

perfectly. Another specimen which I will present is that of tubes and ovaries from a lady aged 38, who had a fibroid about the size of a twelve weeks' pregnancy. She had flowed constantly for three weeks, and was much reduced. Some might consider this a suitable case for electrical treatment, but I did not so judge it, from the fact that there was evident disease of the tubes, and the ovaries were displaced, adherent, and very tender. She had had supporters used for a considerable time, only to aggravate the trouble. I admitted her to my private hospital, and the following day removed the tubes and ovaries. There was double hydrosalpinx, both ovaries were enlarged, cystic, displaced downwards and backwards and adherent.

Their removal was a necessity both to relieve the pain and to cause the uterus to diminish in size. The recovery from the operation was extremely rapid, and she was up in fourteen days.

In regard to the cases whose specimens have been exhibited this evening, I would say that I have had personal knowledge of them all. It is a class of cases hard to diagnose and difficult to treat, and they usually have been through all kinds of treatment, without cure, sometimes without relief, it may be for years, before they come to the surgeon. The operation is not a necessity for life, but it is for a comfortable life, as all patients suffering in this way are invalided considerable of the time, and life is a constant burden to them. Because of this I would consider the operation as clearly indicated, and the results of this series show that everything expected has been realized.

DR. M. ROSENWASSER said: While it is intended to limit the scope of my remarks to reflections on chronic pelvic inflammatory troubles, intimately connected with the subject under discussion, I beg leave to digress for a moment to question the advisability of saving the right appendages in the case of suspected gonorrhoeal salpingitis. The right tube and ovary were bound down by adhesions, requiring considerable force to separate and unfold them; they appeared otherwise healthy. The object in dropping them into the pelvis was to afford the young wife the only remaining chance for a future pregnancy. One would *a priori* expect the bruised and wilted tube, with its raw, thickened walls, to be again enveloped in exuded lymph, its abdominal end occluded and the whole organ glued down to its old or some other neighbor in the pelvis. In due time this tube, so disqualified for performing the function sentimentally reserved for it, will give rise to a series of symptoms of renewed disease which will render its removal as necessary as was that of its fellow. My ominous prediction is based on a paper by Lawson Tait in the May number of the *Amer. Journal of Obstetrics* for 1887, entitled "On the Results of Unilateral Removal of the Uterine

Appendages." In twenty-six unilateral appendages so saved, there was a return of the disease in more than half of the cases; only three subsequently became pregnant. These unpromising results followed, although the appendages remaining had seemed perfectly normal.

DR. CUSHING: I have very little to say to close the discussion. I should like to bring out again the fact that in presenting all these cases and all coming in at once, I do not desire to imply that all such cases are to be rushed into this operation. These are old and neglected cases, most of them from out-of-the-way places where they couldn't get treatment. I had a case from Dr. Adams, of Framingham—pelvis full and hard. I said: "The woman has a home, can hire a girl; better give emollient applications, and wait."

In regard to getting fæcal fistula: of course there is some danger of that. In one of these cases pus was discharged from the rectum. On examining with the finger during the operation I found what I presumed to be adhesions and hardened tissue around the fæcal fistula. I did not disturb it, and she had no trouble from it.

In regard to the matter of puerperal inflammatory affections, I think the profession is going through the same process of education at the hands of Mr. Tait as they did in the case of areolar tissue at the hands of Ruysch.

I think in those cases in which Mr. Tait had the opportunity of operating, within a few days he found the tube enlarged, diseased, and evidence that the septic infection had not got into the lymphatics and run up in that way, as is generally supposed, inflaming the areolar tissue, but that there was septic endometritis; the tubes were enlarged, not occluded; pus runs out and sets the peritoneum on fire—that is the way the case spreads. I saw M. Price operate in a case after abortion. The woman had puerperal fever. The tube was found as big as my wrist, big as a Bologna sausage. Out of that came this nasty foul pus, of which there were pockets in the pelvis. The case was perfectly clear, nothing about the areolar tissue. Pockets extended up to the kidneys. It was a neglected case.

From the results of such operations, I think the profession will go through the same course in regard to puerperal cases as in regard to non-puerperal cases. Where there is an acute case of puerperal fever somebody will take out the diseased tube, if necessary the whole diseased uterus, and in that way save the woman, because the whole uterus may be a sloughing, diphtheritic bag of foul pus. That could be rinsed out from below, but nobody can rinse the tubes out. I think the operation for puerperal fever is going to be to remove the tubes and sometimes the uterus with it, drain and wash out the pelvis, and a good many women will be saved.

FOREIGN CORRESPONDENCE.

LETTER FROM LONDON.

(FROM OUR SPECIAL CORRESPONDENT.)

Sir Joseph Lister: His Operative Work—Abdominal Surgery at the Samaritan Free Hospital for Women—Operative Methods—The Museum in Lincoln's-Inn-Fields.

The hospitals and clinics of the metropolis are so numerous, and the number and variety of patients and diseases so great, that one must of necessity make a selection. Fortunately the days and hours for visits and operations are published, and the visitor need have no difficulty in arranging his visits and thereby utilize all his time. My first visit to Kings' College Hospital was on Friday, the 22d of February, at 2 o'clock, the day and hour of Sir Joseph Lister's clinical lecture. Of course I had an especial desire to see the operative work and to know something of the *personnel* of the man who of all now living has most advanced the science and art of surgery. I remarked as much to Sir Joseph as we entered the operating theatre, saying that I deemed myself fortunate in seeing antiseptic surgery done by the Master, to which he replied with acknowledgement, saying, "the Master is growing old, Doctor, and must ere long leave to others the continuation of his work." The case for operation on this occasion furnished an excellent opportunity to witness the details of his method and the application of the surgical principles bearing his name, it being a case of schirrus of the breast. The operation consisted of complete excision of the right mammary gland and also of the axillary glands adjoining. The spray has long since been omitted from the antiseptic technique. The integument was first thoroughly cleansed and sterilized with a solution of bichloride of mercury, 1 to 500. Towels wrung from a solution of carbolic acid, 1 to 20, were then placed around the site of operation. The instruments and sponges were placed in the solution of carbolic acid, and the same was used for the hands of the operator and his assistant. By a triangular incision the breast was opened and the entire gland containing the tumor removed. The incision was continued into the axilla, and the axillary glands and fascia cleanly removed, the operator relying most upon his fingers and the handle of the scalpel in enucleation. Bleeding vessels were seized with pressure-forceps, and catgut ligatures applied and cut short where required to secure them. Rubber drainage-tubes were placed, the exposed surfaces irrigated with the sublimate solution, and the irrigation continued while the dressing was completed. The latter consisted of the application of silk sutures bringing the flaps together, antiseptic gauze to the wound, all covered with several

layers of light antiseptic gauze, and a bandage retaining all and fixing the arm to the side. As a surgeon Sir Joseph is prompt, deliberate, skillful and self-reliant. Indeed he is, in a word, a thorough-going surgeon. There were two points impressed more particularly upon my mind as I watched the several steps of the operation. The first was the dexterity with which Sir Joseph utilizes the drainage-tube, and what an important feature it is in his technique. In this instance he used three, placed so as to thoroughly drain the extensive surfaces of all fluids. The second point noted was the care bestowed upon preventing admission of air to the wound after uniting the flaps and making the final sublimate irrigation. His care and solicitude regarding this last point were marked, and show that he is firm in his conviction that the air is the medium of microbic infection. As you know, this last premise is the battleground contested so keenly by those who do not adopt in its entirety the Listerian doctrine. The so-called gospel of surgical cleanliness insists upon asepsis as effected by hot water to instruments, hands, etc., but does not regard the air a medium of infection. The fact stands before us, however, that in old hospitals and crowded wards wounds are united without suppuration, joints opened and healed without febrile action under thorough antiseptics. This too with uniformity, in an atmosphere which in the old days carried septic infection in some degree to every wound exposed thereto.

After operating, Sir Joseph Lister kindly took me through his wards where I had the opportunity to see a large number of interesting cases. He removed the dressings from a case of fractured patella in which the joint was opened and fragments wired one week before. The stitches were clipped and removed from a dry, firmly united wound. Two lateral splints secured immobility of the limb, and are retained until union is firm, being removed from time to time for passive motion. In another case the thigh had been amputated, on account of sarcoma, three weeks before, and the temperature chart told the story of continued improvement without febrile action from the date of operation. The case which interested me most in these wards was that of a woman with suppurating hydatid cyst of the liver communicating with the stomach. Three days before Sir Joseph had made an exploratory section, opened, irrigated and drained the sac. The patient now maintained by enema, and presented favorable symptoms. Such interference in an obscure abdominal swelling, associated with grave constitutional symptoms, illustrates genuine conservative surgery, whereas the common practice of giving anodynes in such conditions, called expectant treatment, is anything but conservative. Sir Joseph has the Fergusson and Victoria wards in this excellent hospital, which are always filled with interesting surgical cases of great variety.

Just off Portman Square, at 13 Lower Seymour street, situated immediately on the street, is an unpretentious building which has been the scene of most important events connected with the rise and progress of a great and brilliant department of surgery. A glance is sufficient to assure one that the building was never designed for its present purpose, but that it was a small dwelling-house which has been enlarged and adapted to the demands of its present use. It bears the name of the Samaritan Free Hospital for Women and Children, founded in 1847, with the additional statement that it is supported by voluntary contributions. Entering the reception-room the eye is attracted by a handsome marble bust of Sir Spencer Wells, the eminent consulting surgeon of the hospital. It was here that Sir Spencer conducted through many years with unswerving fidelity and persistence, in the face of fierce opposition and denunciation, those labors in abdominal surgery which laid the foundation for the brilliant achievements of the present age. It must be remembered that after McDowell and Nathan Smith had passed away, ovariectomy lapsed into disrepute, until Wells, in England, and the Atlees, in America, resumed the work and placed the operation upon a firm footing. Sir Spencer has retired from active work at the hospital, and the work is ably continued by Bantock, Thornton, Meredith and others. The first operation I witnessed in the hospital was on February 26, and was by Dr. Bantock. Before being admitted to the operating room all visitors are required to sign a printed statement that they have not recently attended any case of acute infectious disease or post-mortem examination. On entering the room the patient was anesthetized and the operator, assistant and nurse in their respective positions. The hair was shaved from the pubes, and a rubber cloth laid over the patient's body, with an opening over the abdomen. The instruments were placed in trays and covered with hot water. No antiseptic solutions of any kind are employed by Bantock. An incision was quickly made in the median line about 3 inches in length. Before opening the peritoneum all bleeding points were seized with pressure forceps. The peritoneum was seized and nicked, and divided with scissors. The operator then introduced two fingers and thoroughly explored the pelvis. The tumor was an uterine fibroid and was found to have extensive attachments to the sides of the pelvis and pelvic viscera. It was decided to be impracticable to remove it, and the incision was at once closed. Silk-worm gut sutures were introduced with the Hagedorn needle, and the incision neatly closed. A piece of gauze was applied along the wound, a pad of same material superimposed and a broad bandage placed firmly over all.

On March 3, I witnessed a second abdominal section by Bantock. On opening the abdomen

the tumor was found to be a solid tumor of the broad ligament. The peritoneal covering of the tumor was incised, the growth turned out, and a point of firm attachment secured with a single ligature. Considerable venous oozing persisted from the site of the tumor. After packing with sponges for a time, a glass drainage-tube was placed in and the incision closed. The operation was done quite deliberately, great care bestowed upon the toilette of the peritoneum and dressing, and no attempt to curtail time by quick work. Silk-worm gut sutures were used to close the incision. Bantock is most attentive to details, exceedingly neat in all his work and deliberate in dealing with complications. His results are unsurpassed.

On March 6, I saw Mr. Knowsley Thornton do an ovariectomy. Although working in the same hospital, his technique is altogether different from that adopted by Bantock. The patient having been etherized is covered with a large rubber sheet, with a opening over the central part of the abdomen. The instruments, ligatures and sponges are placed in a solution of carbolic acid and the spray (carbolic acid 1 to 24) directed upon the field of operation throughout. An incision about 3 inches long was made and the cyst was entered through dense adhesions. The chocolate-colored contents of the cyst contained numerous, large, soft degenerated clots, seeing which the operator expressed his belief that the tumor would be found to have a twisted pedicle. This proved to be correct. The sac was universally adherent, the attachments being old and very firm. The sac was emptied and thoroughly cleansed, and the work of separation begun. This proved a difficult task. After a faithful effort to secure a hold at the line of incision, it was decided to enlarge the incision and attempt separation from the posterior. The sac was inverted as far as possible and carefully divided upon its posterior part down to omentum and intestines and the work of enucleation begun. The attachments to omentum, intestine and Fallopian tube were very firm and separated with great difficulty. The scissors were required frequently and many ligatures applied. Denuded surfaces bled freely and ligature and sponge-packing constantly applied. Proceeding cautiously, the huge sac was finally brought away. The peritoneum was thoroughly cleansed, all oozing surfaces receiving close attention, and after repeated counting of sponges and forceps the drainage-tube (glass) was placed in Douglas' space and the incision closed. The tube was dressed with sponge and rubber, as usual, but closed carefully by a pad and bandage over all, so as to exclude completely access of air. The pad over the incision was fixed by strong adhesive straps, and bandage over all.

This operation required an hour and thirty minutes and was one of the most difficult I have

ever seen. I have encountered in my own work one such cyst with universal firm adhesions, and could appreciate all the more the difficulties of the situation. I my own case I left behind several portions of the sac attached to the intestines; my patient made a good recovery. Mr. Thornton told me after the operation that several times during the operation he doubted his ability to complete the enucleation. I saw this patient yesterday, eight days after the operation, in advanced convalescence. She had an uninterrupted progress toward recovery, which is already assured.

Of the many admirable features of Mr. Thornton's work, one deserves special mention. I allude to his sponge-packing. He leaves no bleeding points to go back to, but secures them as he proceeds. He uses his sponges to great advantage as means of pressure, to absorb exuded fluids, and to protect the peritoneum in every way. He uses silk altogether for ligatures and sutures.

On March 14 I witnessed an ovariectomy by Dr. Bantock in the morning, and a cholecystotomy by Mr. Thornton in the afternoon. Having outlined the methods of each in abdominal work, I will not go into details by way of repetition.

One of the most interesting and instructive places a medical man can visit in London is the Museum of the Royal College of Surgeons in Lincoln's-Inn-Fields. The collection illustrating extra-uterine foetation is especially rich and particularly interesting at this time, when so much attention is being given the subject. Here also are to be found many specimens from Sir Spencer Wells' extensive experience; one of these from a case of Porro's operation, with nodular fibroid uterus, deserving special mention. One dermoid of the ovary, containing a mass of hair and teeth, is of the Hunterian collection. The collection of uterine and ovarian tumors is very extensive and illustrates many pathological conditions of practical interest. These are all the more instructive by reason of the fact that a history of each in abstract is at hand.

In a few days I go to Bristol to spend a few days with Mr. Greig Smith, and thence to Edinburgh. About April 1 I will go to the Continent, and will write you from Paris or Munich.

L. S. MCMURTRY.

March 15, 1889.

BOOK REVIEWS.

INTESTINAL SURGERY. By N. SENN, M.D., PH.D., Attending Surgeon Milwaukee Hospital; Professor of Principles of Surgery and Surgical Pathology, Rush Medical College, Chicago. Chicago: W. T. Keener. 1889.

This is an octavo volume of 269 pages, printed

and bound in fair style, and contains a republication of the author's very valuable contributions to our knowledge of intestinal injuries and their treatment, by experiments and clinical experience. It contains the lengthy paper on The Surgical Treatment of Intestinal Obstructions, read before the Congress of American Physicians and Surgeons, in 1888; An Experimental Contribution to Intestinal Surgery, etc., reprinted from the *Annals of Surgery*; Rectal Insufflation of Hydrogen Gas, an Infallible Test in the Diagnosis of Injury of the Gastro-Intestinal Canal in Penetrating Wounds of the Abdomen, read in the Surgical Section of the American Medical Association, 1888; and the report of two or three cases illustrating the practical application of the hydrogen gas insufflation.

A MANUAL OF INSTRUCTION IN THE PRINCIPLES OF PROMPT AID TO THE INJURED, Designed for Military and Civil Use. By ALVAH N. DOTY, M.D., Major and Surgeon Ninth Regiment N. G., S. N. Y.; Attending Surgeon to Bellevue Hospital Dispensary, New York. New York: D. Appleton & Co. 1889.

This is a small sized volume of 224 pages, published in good style and fully illustrated. The author says in the preface: "The object of this manual is to instruct those who are desirous of knowing what course to pursue in emergencies, in order that sick or injured may be temporarily relieved. Special effort has been made to arrange the matter and introduce such points as will be of use to the ambulance corps connected with the different military organizations." From a cursory examination of the contents of the book we think the author has succeeded well in accomplishing the object just stated.

WOOD'S MEDICAL AND SURGICAL MONOGRAPHS. Vol. II, No. 1. Contents: "On Diabetes and its Connection with Heart Disease," by JACQUES MAYER, M.D. "Blenorrhœa of the Sexual Organs and its complications," by ERNEST FINGER, M.D. New York: Wm. Wood & Co. April, 1889.

This number of Wood's Monographs contains the two articles named above. They are well translated and interesting. The first occupies 29 pages, the second 275. The second is a complete monograph upon the subject. The advice in regard to treatment is certainly judicious, but we do not learn that any very great advancement has been made by the author over the results of others.

THE STUDENTS' TEXT-BOOK OF THE PRACTICE OF MEDICINE. By ANZEL MONEY, M.D., Lond. London: H. K. Lewis, 1889.

This small hand-book is very well written and free from errors. It is to be commended as a good

but too brief résumé of the subject. In this country at least it is doubtful if there is any need for such small works, which imperfectly cover the subject of the Practice of Medicine.

AMERICAN RESORTS; WITH NOTES UPON THEIR CLIMATE. By BUSHROD W. JAMES, A.M., M.D. With a Translation from the German by Mr. S. Kaufmann of those Chapters of "Die Klimate der Erde," written by Dr. A. Wollkoff, of St. Petersburg, Russia, that relate to North and South America, and the Islands and Oceans contiguous thereto. Philadelphia: F. A. Davis. 1889.

As indicated by the title, this unique and carefully written book is especially adapted for the perusal of invalids and those who desire to preserve good health in a suitable climate. The author, in the preface says, the longer he is engaged in professional work as a physician, the more he is impressed with the importance of the residence of invalids in a suitable climate as an almost indispensable factor in the treatment, prevention and cure of many forms of disease. He is of the opinion that our own country affords sufficient variety and range of climatic conditions to meet the needs of any case where change of climate is desired. He goes on to say: "If we as people, would more generally seek health in our own sanatoria, and our medical men would encourage their patients so to do, the value of these places of retreat for health would soon be appreciated and their fame become widespread."

The chapter on Medical Climatology is especially interesting to the profession, as is also that on the Benefits and Dangers of Health Resorts.

The book is well printed, and reflects credit on both author and publisher.

MISCELLANY.

THE McLEAN COUNTY MEDICAL SOCIETY met in extra session on April 11, 1889, at the office of Drs. Darrah & Corley. There were present Drs. S. T. Anderson, L. A. Burr, E. K. Crothers, C. J. Corley, A. L. Chapman, A. T. Darrah, N. F. Jordan, Wm. Hill, E. P. C. Holderness, E. Mammen, H. Parkhurst, W. L. Pollock, G. M. Smith, J. B. Taylor, F. J. Welch, J. L. White, S. B. Wright.

Dr. Parkhurst occupied the chair. Dr. Jordan stated the object of the meeting, which was to take some action with regard to the proposed repeal by the State Legislature of Section 11 of the Medical Practice Act. On motion the chair appointed Drs. Hill, White and Darrah to prepare resolutions expressive of the sentiments of the members of the Society with reference to the proposed legislation. The committee reported and the Society adopted unanimously the following:

WHEREAS, A bill has been introduced in our State Legislature by one of the Representatives from this county, to repeal Section 11 of the Medical Practice Act, and

WHEREAS, The impression might be conveyed abroad

that the medical profession of McLean County was in accord with the Representative who has offered the bill. Therefore be it

Resolved, That we, the members of the McLean County Medical Society in extra session convened, this, the 11th day of April, 1889, condemn the action of our Representative in his efforts to repeal said Section 11 of the Medical Practice Act, and further, be it

Resolved, That we heartily endorse the Medical Practice Act as it now stands.

Drs. J. L. White and A. T. Darrah were appointed to visit the Illinois State Legislature in the interest of the Medical Practice Act as it now stands.

C. J. CORLEY, M.D., Secretary.

ADMISSION OF AIR TO ROOMS.—Air should be introduced and removed at those parts of the room where it would not cause a sensible draught. Air flowing against the body at, or even somewhat above the temperature of the air of the room will cause an inconvenient draft, from the fact that, as it removes the moisture of the body, it causes evaporation or a sensation of cold. Air should never, as a rule, be introduced at or close to the floor level. The opening would be liable to be fouled with sweepings and dirt. The air, unless very much above the temperature of the air of the room, would produce a sensation of cold to the feet. It may be regarded as an axiom in ventilating and warming, that the feet should be kept warm and the head cool.

The orifices at which air is admitted should be above the level of the heads of the persons occupying the room. The current of inflowing air should be directed toward the ceiling, and should either be as much subdivided as possible by means of numerous orifices, or be admitted through conical openings with the smaller opening toward the outer air and the larger openings toward the room, by which means the air of the entering current is very rapidly dispersed. Air admitted near the ceiling very soon ceases to exist as a distinct current, and will be found at a very short distance from the inlet to have mingled with the general mass of the air and to have attained the temperature of the room, partly owing to the longer mass of air in the room with which the inflowing current mingles, partly to the action of gravity in cases where the inflowing air is colder than the air in the room. —*Sanitary News*, April 13, 1889.

A NEW CHAIR.—A Chair of Physical Examination for Life Insurance has been created in the University of Vermont. Is there anything in the physical examinations for life insurance that differs so much from the application of physical examinations for diagnostic purposes generally, that a special Chair for its teaching is required?

THE ANNUAL MEETING of the Association of Acting Assistant Surgeons of the U. S. Army will be held in the Casino at Newport, R. I., Monday, June, 24, 1889, at 8 P.M. Members of the Association are cordially invited to read, or present papers concerning the history and the welfare of the corps. Members who intend to be present are requested to notify the Recorder at the earliest possible date. Although few Acting Assistant Surgeons can be present at the meeting, the Association will discuss the best methods to aid in improving the status of those who are now serving, and will do everything in its power for their welfare. The Secretary, or Recorder, is W. Thornton Parker, M.D., 322 Benefit St., Providence, R. I.

MEDICAL ASSOCIATION OF THE DISTRICT OF COLUMBIA.—At the recent regular annual meeting of the Medical Association of the District of Columbia the following officers were elected for the ensuing year: President, Jas. T. Young, M.D.; Vice-Presidents, A. F. A. King, M.D., Swan M. Burnett, M.D.; Secretary, Geo. C. Ober, M.D., Treasurer, Sam'l S. Adams, M.D.; Censors, Drs. H. D.

Fry, C. W. Richardson, L. K. Beatty; Counselors, Drs. T. W. H. Lovejoy, Kleinschmidt, Smith, Acker, Cook, Dunn, McArdle, Prentiss and Johnson.

THE TWENTY-SECOND ANNUAL SESSION of the Medical Society of the State of West Virginia will be held at White Sulphur Springs, W. Va., on July 17, 18 and 19, 1889. The prospects are that this will be a large and interesting meeting. Dr. J. L. Fullerton, Secretary of the Society, Charleston, W. Va., will be glad to give any information desired.

THE MICHIGAN STATE MEDICAL SOCIETY will hold its next annual meeting in Kalamazoo, May 9th and 10th. The Address on Medicine will be given by Dr. H. F. Lyster; the Address on Surgery by Dr. Newman Kiefer; and the Address on Obstetrics and Gynecology by Dr. E. W. Jenks. Complete arrangements are made for the accommodation of members and a full meeting is expected.

PAMPHLETS RECEIVED.

Baker, A. R., M.D., Cleveland, Ohio. *Opening Address Medical Department of the University of Wooster, February, 27, 1889.* Reprint from the Cleveland Medical Gazette.

Judson, A. B., M.D., New York. *The Question of Interfering with the Abscesses of Hip Disease.* Reprint from the New York Medical Journal.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from April 6, 1889, to April 12, 1889.

PROMOTIONS.

Charles C. Byrne, Surgeon U. S. Army, promoted Surgeon, with the rank of Lt.-Col., to rank from March 29, 1889.

Curtis E. Munn, promoted from Asst. Surgeon to Surgeon, with the rank of Major, to rank from March 29, 1889.

By direction of the President, Capt. Paul R. Brown, Asst. Surgeon, will report in person to Brig.-Gen. John R. Brooke, President of the Army Retiring Board at Omaha, Neb., for examination by the Board. Par. 9, S. O. 50, A. G. O., Washington, April 6, 1889.

By direction of the Secretary of War, leave of absence for six months is granted Capt. Charles S. Black, Asst. Surgeon, to take effect after the arrival at Ft. Sidney, Neb., of Acting Asst. Surgeon Robert P. Finley. Par. 14, S. O. 78, A. G. O., Washington, April 4, 1889.

By direction of the President, the State of Wisconsin is transferred from the department of the East to the Department of Dakota. G. O. 36, A. G. O., Washington, April 6, 1889.

Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending April 13, 1889.

P. A. Surgeon A. C. Heffenger, found unfit for duty at present, by Retiring Board, but not permanently incapacitated for active service, and granted one year's leave of absence for medical treatment.

P. A. Surgeon W. R. DuBose, detached from the U. S. S. "Constellation" and ordered to the practice ship "Jamestown."

C. H. T. Lowndes, commissioned an Asst. Surgeon in the U. S. Navy March 13, 1889.

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine-Hospital Service, for the Two Weeks Ending April 13, 1889.

Surgeon John Godfrey, to proceed to Poughkeepsie, N. Y., on special duty. April 10, 1889.

P. A. Surgeon F. W. Mead, to report in person to the Supervising Surgeon-General, April 3, 1889. Detailed as Acting Chief Clerk Marine Hospital Bureau, and attending surgeon, port of Georgetown, D. C. April 10, 1889.

P. A. Surgeon W. A. Wheeler, relieved from duty at Buffalo, N. Y., to assume charge of the Service at Norfolk, Va. April 3, 1889.

P. A. Surgeon S. C. Devan, relieved from duty as Acting Chief Clerk, Marine Hospital Bureau, and attending surgeon; to assume charge of the Service at Buffalo, N. Y. April 3 and 12, 1889.

Asst. Surgeon W. J. Pettus, granted leave of absence for four days. April 6, 1889.

Asst. Surgeon J. B. Stoner, to rejoin station (New York) as soon as practicable. April 11, 1889.

POPULAR FALLACIES REGARDING ATHLETES AND ATHLETICS.

BY IRVING ROSSE, M.D.,

OF WASHINGTON, D. C.

As a branch of medicine that has for its object the bringing of man to a greater state of physical perfection, the question of athletics has for the more advanced and liberal minded of our profession the highest interest.

In our parliamentary city where so many persons suffer from the effect of sedentary life, the athletic remedy seems to be the only sensible one, and it is daily becoming more apparent that a growing demand for athletics exists among the bright young men of the civil service who are fast replacing the sick, the infirm, and the political paretics that formerly filled the government departments. It is, therefore, with much gratification that we can point to the organizations of the Columbia Athletic Club of 450 members, and note the very favorable auspices under which it takes departure, owing to the liberality of a wealthy citizen, Mr. John McLean, formerly of Cincinnati.

The War Department, too, shows increased concern in the somatic efficiency of the material composing the Army. Dr. Greenleaf, of the Surgeon-General's office, has lately interested himself in the study of Dr. Sargent's anthropometric system with a view to its general introduction into the service. Any measure that will raise the physical standard in our little army is, of course, worthy of the highest praise. Even West Point men are physically far below the popular conception. A large proportion of them cannot swim, and generally speaking, the educational means of elevating the physical powers are not at the Military Academy what they should be. Acute indigestion and affections of the alimentary canal are more common than is generally supposed among the cadets, and inability to support a little fatigue and atmospheric vicissitude, such as that encountered at the inauguration of General Grant in March, 1873, does not give a very favorable exhibit, judging from the sick reports of that month, which shows a total of

195, while a larger number of artillerymen, nearly all of whom got wet the night before the inauguration, shows but thirty-three sick. The proportion of sick among the naval cadets, also present, was notably less—a circumstance that speaks well for the reorganization of Admiral Porter, who, by the way, has correct and enthusiastic notions in regard to physical culture, which have been introduced at the Academy. To any one witnessing the parade on the forementioned occasion the fresh, ruddy appearance of the midshipmen was in striking contrast to that of the cadets. A few years since at the Artillery school at Fort Monroe, of fifty-three officers, mostly young graduates, only eight could swim, and but three well; three more knew a little about boxing, and two could put up the dumb bell of sixty pounds—facts that go to show that military drill alone is a poor means to attain the athletic habit of body so becoming to a soldier.

Aside from military considerations, it may be laid down as an axiom, that in order to have a strong nation the palestric element must enter. Many popular fallacies concerning athletes and athletics still prevail to a great extent, not only in the general community, but among medical men, and this mainly for the reason that heretofore most of the published opinions relatively thereto have emanated either from athletes who knew nothing of medicine, or from physicians who were not athletes. In these days when errors are being dispelled and the mists of prehistoric times are finally rolling away, a thoughtful man is often astonished at the persistency of many popular fallacies, which, as a matter of fact, are no better than the groundless superstitions about Friday, thirteen at table, or the alleged coincidence of the red-headed girl and the grey horse—all of which exemplifications may be classed in the same category of sophistical reasoning with much that has been written and accepted respecting athletics.

Physicians are often accused of their deficiencies in the science of logic, and in many instances very justly so, but I am not at all prepared to believe that as a class they are any more deficient in this respect than other people. Without attempting to take up their cause, I will admit that the records of medical literature are

filled with rubbish, and that medicine continues to deserve the designation of an art rather than that of a science, mainly for the reason that some medical men will rush into print with no suggestion as to the insufficiency of the evidence adduced in order to establish a new truth. This gives rise to that common and most fatal of all errors, a post-hoc conclusion. If I were writing a book on errors in reasoning, and wanted to exemplify false ratiocination or deduction, I do not know of a more prolific source than that of sciolistic medicine, from which I might borrow pathological illustrations so to speak.

I might also quote various authors who, in regard to physical exercises, have carried their invectives so far as to have substituted prejudice for reason, and have generalized from insufficient observation.

Mr. Wilkie Collins' attempt to bring athletics into disrepute in "Man and Wife" is but a vulgarization of the professional opinion held and promulgated by many physicians; and it needs but a superficial acquaintance with current medical literature, to find the most unqualified condemnation of athletics, and the warnings against their evil consequences.

One writer says they cause hernia and aneurism, another heart disease, while a third asserts that athletes soon grow stale and are short lived. These, with many other alleged hurtful consequences have been put forward with all the pretension of spectacted gravity to give them currency. It is easy to understand from what point of view Mr. Collins regards athletics. Being a small, round shouldered man, with a shambling gait, it is not surprising that his connotation should assume something of a lame man's opinion of dancing, but observation and experience do not justify the deductions of physicians who stigmatize athletics. I have known many hundreds of athletes in different parts of the world, and I have yet to learn of more than one case of hernia resulting from over-exertion. The mechanical impossibility of producing a hernia on a dead body, even if the abdomen be forcibly compressed, if gaps be made in its walls, and the belly subjected to several hundred-weight, and even to horse-power, would seem to demonstrate that hernias do not originate from violent muscular efforts, but are already present, being generally congenital.

Concerning the prevalence of aneurism and heart disease among athletes, there are many current errors that reflect the common judgment. A noted athlete dies of heart trouble, phthisis or paralysis, upon which popular judgment, and regrettable to say, the unthinking medical man draw a post-hoc conclusion. It requires but little thought to upset this fallacy.

Athletes, as a class, are not short lived. On the contrary, many who have led sober and regular

lives have attained extreme old age. It is hardly necessary to refer to the historical mention of Socrates, who at the age of 60, an age when officers of the Army and Navy are retired, served as hoplite in the Peloponnesian war, and though covered with heavy armor took upon his shoulders a wounded man whom he carried into camp while being pursued by the enemy.

In England the general impression among many is that the occupation of pugilist, instead of being hurtful, is a remarkably healthy one, and it is generally admitted that they live longer than any other men. This assertion is supported by facts that are recognized and commented upon by Dr. Royer-Collard in his celebrated work on *Organoplastie Hygènique*. We have numerous instances of old athletes who have not become stale. Many persons have heard of old Gabe Ravel, who at a very advanced age, turned back sommersaults. Frenchmen also know of Madame Saqui, who at the age of 70, in Paris, walked a wire stretched at a great height. Circus men are not only healthy, but long lived. The famous clown of London, Joe Wallet, was ten years ago considerably over 70, and as lively and active as he was forty years previously. Old Orde lived to considerably over 90, and a short time before his death, gave bareback performances. Batty was in the business till past 70, and Franks some years since was tumbling somersaults and posturing at Hengler's considerably over 60, and as fresh as a daisy. An inquiry extending over more than fifty years shows that the men who rowed in the Oxford and Cambridge crews lived on an average longer than the men who did not row. The former champion Greco-Roman wrestler, William Miller, informs me that he knows of many athletes who have attained a good old age, and his opinion, the one held generally by professionals, is that the proper employment of athletics united to a regular life is highly conducive to longevity. Mr. Phineas T. Barnum tells me that he considers the exercises of a well conducted circus to be of the most healthy character, developing the performers chiefly into muscle, and making them the most vigorous people living. As a class, they are long lived, in fact more so than persons in ordinary occupations, especially when they have been temperate. Among very old English pugilists may be mentioned Belasco, Adams, and the older Stevenson. A few years since the sporting papers recorded the death, at an advanced age, of Owen Swift, whose extraordinary career as a prize fighter, may be seen in the musty old files of fifty years ago, he then being in the thirties, while Tom Sayers was still in swaddling clothes, and had already killed one man before Jem Mace was born. Some time since the death of Bendigo, who passed from the prize ring to the pulpit, was reported at 68 years; and during the last year

two other noted pugilists have died at advanced age. One of them, Jem Ward, born in London on Christmas day, 1800, was perhaps the oldest boxer in the world. Most New Yorkers can recall Ottignon and "Pop" Whittaker in this connection. I know yet of an old man of 75, who still puts up his hands in a surprising manner and, barring eye sight, is well preserved.

A few years since, in San Francisco, I was walking in the street with the Secretary of the Olympic Club, who talked to me of this very matter, when we came across a very old man, whom he pointed out as a corroborative instance of what he was telling me. This man in days gone by, had been an athlete of the most violent kind, in fact, a man who had misused athletics by such feats as walking a thousand miles in a thousand hours and other like senseless performances.

The untimely death of several notables who have figured extensively in the athletic world during the last fifteen or twenty years, has, in every instance, as far as could be ascertained, been owing to preventable or to immoral causes, the nature of which it is not necessary here to specify. The possibility of over-exertion being the cause of impaired health in after-life is exceedingly problematical.

The result is rather owing to immoderate indulgence and to the neglect of simple hygienic rules. It is, of course, possible for one to abuse and overdo physical exercise, just as one may do by eating too much bread and thereby poisoning oneself; but enlightened common sense would say that in a misuse of this kind, it is the man, not the bread or the athletics that should bear the blame.

On this subject, Dr. Sargent, of Harvard, tells me that he thinks it but fair to state that in many instances the early demise of athletes cannot be directly attributed so much to the results of athletic work as to the free indulgence of gross appetites and passions which they have not the moral power to control, and where this was not the case, they lived beyond the average. From extensive personal knowledge he knows of but two deaths attributable to over-exertion; the others were from dissipation, and its train of attendant evils. Inquiry seems to establish the fact that the occupation of athletics is more favorable to longevity than many of the mechanical and industrial pursuits, notably those of shoemaker, tailor, baker, clerk or miner; and if further trust may be placed in vital statistics, merchants, capitalists, financiers and persons engaged in the transfer of property have not the same lease of life.

I have now put in light a sufficient number of facts the very opposite from those of other observers, who seem to have limited their sphere of action to but one side of the question.

My collection of facts may be wanting in delicate analysis, and the homogeneity and regularity indispensable to science; but the observation of such as I have brought forward, even when observed without the aid of method, forces upon us the induction that no good reason exists for the wholesale condemnation of athletics. On the contrary, it is evident that the healthy exercise of the physical powers, is one of the necessary pastimes of a manly and vigorous race; and that next to food and sleep athletics has the largest share in the recreation of human life. It is, therefore, high time that the conventional opinion of certain medical men and of some educators on this subject should be set aside, and that all the manly sports should be encouraged, and fostered with a view to promote qualities that intimately concern not only the happiness and usefulness of individual life, but also the good of society, and the future of the human race.

SCARLATINIFORM RASHES.

Read before the St. Louis Medico-Chirurgical Society, Oct. 30, 1888.

BY JOSEPH GRINDON, M.D.,

LECTURER ON DISEASES OF THE SKIN AT THE ST. LOUIS MEDICAL COLLEGE.

There is made no claim of originality for this paper, as it consists simply in a re-arrangement of what is to be found in the text-books and current literature of the day. My object has been to group together in this form those erythemata and other diseases of the skin which may by their resemblance to scarlet fever lead to errors of diagnosis, believing that the setting of old truths in a new light is not devoid of benefit.

The early *roseola of syphilis* may somewhat resemble scarlatina, especially when attended with throat complications and syphilitic fever. It is not necessary to do more than allude to the possibility of mistake here.

It was long since noted, by Sir James Paget, that the wounded are specially predisposed to scarlet fever. This was confirmed later by many eminent French and English observers. Mr. Holmes, while admitting the fact, contended that many so-called cases of "surgical scarlet fever" were really due to septicæmia or pyæmia, to the absorption of some other than the true scarlatinous poison. I believe that the predisposition above spoken of, and also the existence of a *scarlatiniform septicæmic rash*, are now admitted on all sides, but there seems still to be considerable difference of opinion as to the relative prevalence of the two.

The appearance of a scarlet rash in a puerperal woman gives scope for the exercise of one's diagnostic powers. The date of delivery marks a change in the receptivity of woman for the contagious diseases. The pregnant female is less,

and the puerperal female is *more* liable than others. Not only so, but the disease is apt to run a malignant course in the latter condition. It is in the occasionally mild cases, however, of scarlatina puerperalis that the difficulties of differentiation arise. For there has been observed a septicæmic rash in this condition essentially the same as that due to sepsis occurring as a surgical complication. It may present, as in a case observed by myself some years ago at the Female Hospital, a most deceptive counterfeit of true scarlatina. Dr. J. C. Thomas, in the *Journal of Cutaneous and Venereal Diseases* for January, 1885, gives the points of differential diagnosis as follows: "The absence of the history of the prodromata of scarlatina, the absence of throat symptoms, the moderate temperature and the moderate amount of constitutional irritation, the history of the development and decline of the eruption and the character of the desquamation." The last is apt to be in large scales and strips. The fever is slight and other evidences of sepsis usually not pronounced. In the three cases reported by the writer just mentioned the rash appeared on the second, fifth and ninth post-partum day, severally. The eruption remained out seven or eight days in these cases. Duhring thinks the rash appears between the third and fifth days.

The period of invasion or first day or two of eruption of variola is sometimes marked by the appearance of an *adventitious rash* which may be roseolar, urticarial or petechial, but which at times, as in a case of mine, simulates true scarlatina of the most intense type. It should be remembered, however, that smallpox and scarlet fever may occur in the same individual at the same time. The adventitious erythema, however, is more short-lived than the exanthem it mimics, and will also be without a history of scarlatinal contagion. Where both contagia are present one may well pause before giving a decided opinion. It was once my fortune to have under my care a family consisting of a mother and three children. The mother and one child had smallpox, another child at the same time had unmistakable scarlet fever, and the third died exsanguine from repeated hæmorrhages from various mucous orifices. Had it not been for a few abortive papules about the wrists, the diagnosis between scarlatina hæmorrhagica and variola hæmorrhagica would not have been made.

Diphtheria is at times accompanied by a cutaneous manifestation which may be scarlatiniform, although oftener roseolar. A case of this kind was reported by me, and another by Dr. Hermann, before this Society last April. Bearing in mind the fact that scarlatina anginosa may present patches of necrotic membrane on the fauces, palate, etc., constituting the so-called "scarlatinal diphtheria," in which the membrane is essentially identical with that found in primary diphtheria,

the difference being, according to most observers, purely etiological, it can easily be seen how difficult the diagnosis between scarlatinal diphtheria and diphtheria with scarlatiniform erythema may become, especially when we add another complicating factor to the problem, which is, that true diphtheria and scarlatina may co-exist in the same individual. J. Lewis Smith claims to have seen cases of uncomplicated primary diphtheria derived from the last named complication, thus establishing, if we accept the observation, the true diphtheritic nature of the process in the last named class of cases.

As to the establishment of the separate identity of "scarlatinal diphtheria" and diphtheria with scarlatiniform rash, we must remember that although there would probably be in both adenopathy and perhaps albumiuria, that in the first named disease there is never, according to Koven and Hensch, secondary paralysis. Of course there may be paresis from inflammation, or necrosis of muscular tissue. The fugacious character of the symptomatic erythema would be its chief diagnostic feature. There have been recognized two forms, one, early, accompanied with but little fever, and another, late, the effect of sepsis.

Dr. Brocq, of Paris, in an article on "Desquamative Scarlatiniform Erythema," in the *Journal of Cutaneous and Venereal Diseases* for August, 1885, from which I draw largely, says that this affection "is characterized by an initial stage of pronounced fever, similar to that of scarlatina; by an intense redness of the entire cutaneous surface, which subsequently peels off in flakes; and by the occurrence of complete recovery in from three to six weeks." After the subsidence of the primary attack the disease tends to reappear three or four times, or even oftener. Hence the word "relapsing" has been prefixed to its designation. The doctor had at the date mentioned collected 14 cases.

The eruption is preceded by a precursory stage of variable duration, sometimes lasting several days, during which there are feelings of discomfort and fatigue, and rigors followed by high fever, attended at times with violent head and back ache.

The point at which the cutaneous lesion first appears is sometimes on the upper and sometimes on the lower part of the body, usually diffusing itself over the whole surface in twenty-four hours, although it may take as long as four to six days. The face, as in scarlatina, is usually not so red as the rest of the body. In a general way it may be said that the extensor surfaces are of lighter tinge than the flexor. The abdomen, however, is often quite dark. The redness can be temporarily obliterated by pressure of the finger.

The time at which desquamation appears can not be accurately determined, but it is often three or four days after the eruption has reached its

height, and while it is still in full florescence. This phenomenon is first noticed at the regions earliest implicated and is remarkable for its flaky character, the flakes being large, thin and transparent, and for its abundance. In one case mentioned by the author from whom the main facts of this description are taken, three litres of scales were collected in five days. On the face the scales are smallest, in fact furfuraceous, and are largest about the neck. On the palms the same desquamation *en masse* may take place as is observed in scarlatina. With the outset of desquamation the constitutional symptoms disappear. The mucous membranes of the throat and eyes are sometimes reddened.

The period of scaling averages between two and three weeks of duration.

The diagnosis between this disease and scarlatina is difficult when we have to do with a first attack, and sometimes only a retrospective diagnosis will be possible. But in this disease the onset is less abrupt than in scarlet fever, the redness of the skin is more marked and often persists after the eighth day, desquamation is more abundant, is lamellated, and frequently repeated. The disease is non-contagious, and nephritis and adenopathy are never present. Cases of this kind have been reported by Besnier, Féréol, Duhring and others, and seem to have been included by Bateman under the head of pityriasis rubra, a name since restricted to a different and much graver affection.

Hardy has described a *scarlatiniform erythema*, the *roseola scarlatiniforme* of Bazin and *erythema punctatum* of McCall Anderson which lasts from 24 to 48 hours, presents an appearance of the skin almost identical with that of scarlatina, and is followed by some scaling off. It seems always to depend upon gastric derangement and is non-contagious. The points which distinguish it from scarlatina are, that the pulse remains nearly at the normal, the tongue continues to present its normal appearance, and that there are no sequelæ of any kind. Of course it is as liable to occur in one having had scarlatina as in anyone else, and, on the other hand, confers no immunity against that disease.

The early stages of *pityriasis rubra*, or *dermatitis exfoliative*, may be mistaken for scarlatina. But in the affection known under these two names there are no prodromata, the temperature is generally lower, and the course of the disease, except just at first, altogether different.

I have reserved a brief notice of the best marked of the scarlatiniform rashes due to the ingestion of drugs for the end of this paper. A thorough treatment of even this limited portion of the subject of dermatitis medicamentosa would exceed my powers of performance and yours of attention. The subject is growing every day, because, first, it is not long since it began to receive

the attention it deserves, and second, from its very nature it ever must grow. As new drugs are introduced new drug eruptions will be heard of.

Perhaps the most truly scarlatiniform of these is that produced by *belladonna* or *atropia*. It was this which led believers in the doctrine of similars to use the drug in the treatment and prophylaxis of scarlatina. In this, as in all forms of medicamentous dermatitis, personal idiosyncrasy is the chief etiological factor, the most marked effects sometimes following the smallest doses. Children are said to be more obnoxious to this accident than adults, but that it is by no means confined to them may be illustrated by the following observation.

A lady 67 years of age had a few drops of a solution of the sulphate of atropia, 2 grs. to the ounce, dropped into each eye. She soon complained of dizziness, intense faucial dryness and general pruritus. On examination I found both pupils dilated *ad maximum*, and the face and neck of a bright scarlet hue, which gradually faded and disappeared in something less than twenty-four hours. Six months later the same procedure was followed by the same results. It is manifestly unnecessary here to indicate points of diagnostic difference, but I may be permitted to call attention to the fact that the belladonna eruption is most profuse where the exanthem is usually palest, *i. e.*, about the face.

The *chloral* eruption is sometimes much like that last described, lasts from a half to four hours, and may be followed within twenty-four hours by light desquamation. The occurrence of a relapse after discontinuance of the medicine has been observed and need not cause us to change our minds as to the drug and the erythema bearing to each other the relation of cause and effect.

The cutaneous accident due to the ingestion or absorption of *mercury* is often scarlatiniform. A dose of 2 grains of calomel has been known to bring out a copious eruption.

Opium and *morphine* bring out at times a rash of this type, which, like scarlatina, is apt to be best marked on the flexor surfaces. It is occasionally followed by desquamation, glove and stocking casts having been shed off as in the exanthem. To make the resemblance greater, there is at times an erythematous inflammation of the pharynx.

The *quinine* eruption may at times closely simulate scarlatina. The absence of characteristic prodromata, of sore throat, of the rapid pulse and the characteristic tongue should aid us in detecting the counterfeit. Here again there has been observed desquamation similar to that following the opium rash, as in a case reported to this Society by Dr. Wolfner.

The eruption due to *oil of turpentine* is likewise sometimes followed by desquamation.

Digitalis, *stramonium*, *strychnia* and *salicylic acid*

might also be mentioned here. The list of drugs which have been known to produce eruptions having some resemblance to that of scarlet fever might be greatly extended, but my desire is to mention only those the effects of which would be most likely to mislead in the particular direction now under consideration. I suppose it is well understood that the medicaments mentioned may produce effects differing widely from those which have been described. In fact it would seem that the particular type of the cutaneous accident depends more upon individual peculiarity than upon the drug administered.

I am chiefly indebted for the facts mentioned in the last part of this brief review to the writings of Arthur van Harlingen and P. A. Morrow, which all may consult with benefit.

AN INTRODUCTION TO THE STUDY OF PNEUMONIC FEVER.

BY EDWARD F. WELLS, M.D.

FIFTH PAPER.—GEOGRAPHY.

Medical geography is, equally with historical pathology, one of the most fruitful means of etiological research. It enables us to become acquainted with the different regions of the globe in which certain diseases prevail, and thus allows upon the grandest scale the study of cosmic, tellurial and even anthropological conditions that may favor or hinder their development.¹

Pneumonic fever prevails in every part of the world, but, as is the case with all other maladies, it is more common in some localities than in others.² It is more prevalent in temperate than in either frigid or torrid regions. Beginning at the poles, its frequency increases in a gradual manner until the maximum is attained at a certain latitude in either temperate zone, and from these points it diminishes as we approach the equator, so that in some tropical countries the malady is somewhat of a nosological rarity.³ This is only true as a general proposition, and there can be found so many apparent exceptions that it is quite clear that latitude alone has no influence over the prevalence of the disease.

The influence of latitude upon the prevalence of pneumonic fever is shown in the following table:

Sanders' claims that in North America pneumonic fever increases in frequency from east to west, whilst in Europe it does so from west to east, but a glance at Table XI shows that longitude alone has but little influence over the prevalence of the disease.

TABLE XI.—SHOWING LONGITUDINAL PREVALENCE OF PNEUMONIC FEVER.

Pneumonic fever is met with more frequently on land than upon the open sea or the smaller sea-islands,⁶ although this is denied by some.⁶

The location of cities in proximity to large bodies of water does not appear to exert that influence over the prevalence of pneumonic fever which one would be led to expect.

Thus, 31 lake or inland seaports show a death-rate of 1.35 per 1,000 inhabitants, annually; 90 inland cities, 1.29 per 1,000; and 58 ocean ports, 1.20 per 1,000. An average of the 179 cities gives an annual mortality of 1.26 per 1,000 of population.

It might be a natural supposition that altitude would exercise a marked influence over the prevalence of pneumonic fever, and yet the statistical material at our disposal is of such a nature as to preclude the arrival at a positive conclusion regarding it.

At high altitudes the atmospheric pressure is very considerably diminished, and if the country is, in addition, mountainous, the inhabitants, in ascending the heights, require increased action of the lungs with a corresponding acceleration of the circulation. Under such conditions it might be supposed that the lungs would be in a condition favorable for the development of pneumonic fever, and that this disease is especially prevalent in such localities is affirmed by many authors.⁷

Thus Lombard,⁸ basing his opinion upon the impression of a large number of the practitioners of the mountain tops and high uplands of Swit-

Ziemssen, *Präger Vierteljahrsschr.*, 1858; Hermann, *Lungenentzündung*, etc., S. 6; Swett, *Dis. Chest*, p. 81; Lebert, *Klinik d. Brustkrankh.*, Tübingen, 1874, Bd. i, S. 710; Lépine, *Die Acute lobäre Pneumonie*, Wein, 1883, S. 21; Hirsch, *Handb. d. Hist. u. Geog. zerland and Germany, claims that the prevalence of pneumonic fever gradually increases as we ascend from the sea level, and is met with most frequently in localities of the greatest altitude. Hirsch⁹ says that the disease is very common in the South American Andes, the mountain lands of Abyssinia and the elevated plains of Arabia. It is very prevalent in the Allegheny mountains¹⁰ and on the top of Mont Ceniz.¹¹

On the contrary, it is rare in the elevated cities of Boulder,¹² Denver,¹³ Ft. Bridger,¹⁴ Sorocco¹⁵ and Mexico,¹⁶ and it has even been claimed that there is a lessening of the prevalence as we ascend toward the highest inhabited mountain regions.¹⁷

The relations of altitude and pneumonic fever are shown in the following table:¹⁸

TABLE XII.—SHOWING RELATION BETWEEN ALTITUDE AND THE PREVALENCE OF PNEUMONIC FEVER.

185	Augusta	3,00		
285	Trieste	2,30	Average	1,27

Although pneumonic fever may not be met with so frequently at great elevations, yet in such localities it is very fatal.²¹ Under these circumstances the death-rate bears a large proportion to the actual number of cases or the prevalence.

At an elevation of from 4,000 to 5,000 feet the disease is, probably, not so common as at a lower level, but it is more severe. At an elevation of 7,000 feet or more, epidemics are frequent and the malady is almost always sthenic and malignant, and at an elevation of 10,000 feet it is usually fatal in about three days.²²

EUROPE.—In Europe pneumonic fever prevails

to an extent slightly above the general average, the death-rate being 1.31 per 1,000 inhabitants.²³

Iceland.—On this island pneumonic fever, in common with other thoracic diseases, is comparatively rare,²⁴ it being the cause of 3.2 per cent. of all deaths and an annual mortality of .79 per 1,000 inhabitants.²⁵ In 1863 there prevailed an extensive and very fatal epidemic.²⁶

Norway and Sweden.—In these countries this malady is quite common,²⁷ but varying considerably in different localities.²⁸ The disease pursues an acute course, and when fatal it is rapidly so.²⁹

Faro Islands.—Here pneumonic fever is less prevalent than the average,³⁰ causing only 4.5 per cent. of the deaths and an annual mortality of .71 per 1,000 persons.³¹

Russia.—The disease causes, in this land, 1.5 deaths per 1,000 of population, although in some parts of the country it is much more prevalent.³²

Denmark.—In this country pneumonic fever prevails somewhat above the average, being responsible for 6.4 per cent. of the deaths and 1.57 deaths per 1,000 persons per annum,³³ although it is higher in Copenhagen.³⁴

Germany.—Throughout the empire this disease prevails very generally, and slightly above the average—a mortality of 1.34 per 1,000 inhabitants per annum.³⁵

In the imperial army, during a period of eight years, pneumonic fever caused 12.3 per cent. of the deaths, although the mortality from this cause was but .47 per 1,000 of force.³⁶ At the Germerheim Garrison, during 26 years, it caused 7.6 per cent. of deaths and a loss of .40 per 1,000 soldiers.³⁷

In Prussia, 3.9 per cent. of the deaths in the kingdom at large, and 7.5 per cent. in 14 of her large cities, arise from this malady.³⁸ In Berlin, during 26 years the annual death-rate was 1.12 per 1,000 of population.³⁹ Breslau gives a death-

²³ Sanders—Am. Jour. Med. Sci., July, 1882—gives the proportion as 1.57 per 1,000.

¹⁷ Ziemssen, Präger Vierteljahrsschr., 1838; Sanders, l. c.

¹⁸ Facts regarding height were obtained from Drake, Dis. Int. Valley, N. A., Vol. i, Cincinnati, 1850; Fossagrave, Hyg. et Ass. des Villes, Paris, 1874, p. 75; Sanders, Am. Jour. Med. Sci., 1882; and by correspondence.

¹⁹ This is from Sanders—op. cit.—but is probably an error.

²⁰ Chamberlain—N. E. Med. Monthly, 1883—erroneously credits Denver with the lowest death rate from this disease of any city in the United States, and Sanders gives the death rate at .34.

²¹ Lombard—Climate de Montagnes, p. 70—claims that most of the very fatal epidemics occur in the high mountain valleys, with the spring melting of the snow and ice.

²² Milliken, Cincinnati Lancet and Clinic, Dec. 16, 1882, p. 578. See also Jayne, Phila. Med. News, Nov. 10, 1888, p. 520.

rate of 1.20 per 1,000 inhabitants.⁴⁰ In Hamburg the disease is very prevalent.⁴¹ It is very common in Kiel and Tübingen,⁴² and Halle is peculiarly afflicted, showing an average annual death-rate of 2.29 per 1,000 persons, in a series of ten years.⁴³ Bavaria also shows a high mortality rate from this disease.⁴⁴

Austro-Hungary.—In this country the malady prevails to an extent considerably beyond the average—6.9 per cent. of deaths and 2.42 per 1,000 of population.⁴⁵ It is very common both in Vienna⁴⁶ and Budapest.⁴⁷

Switzerland suffers a death-rate from this disease of 1.50 per 1,000 inhabitants, and 7.8 per cent. of her mortality is due to this cause.⁴⁸ The proportion in the Canton Zürich⁴⁹ and in the cities of Zürich⁵⁰ and Geneva⁵¹ are still greater.

Holland is afflicted by this disease in a degree considerably greater than the average,⁵² although it is less prevalent in Ghent.⁵³

Belgium, as a country, does not suffer severely from pneumonic fever, although her two largest cities are slightly above the average.⁵⁴

Great Britain and Ireland.—In Scotland this disease prevails considerably below the average,⁵⁵ even in the cities,⁵⁶ whilst in England and Wales the prevalence is an average one,⁵⁷ being more common in London,⁵⁸ Bristol,⁵⁹ Bolton,⁶⁰ Kendal,⁶¹ Malvern,⁶² Cornwall,⁶³ and some other localities, and less prevalent in Cheltenham,⁶⁴ Sidmouth,⁶⁵ Guernsey⁶⁶ and Devonshire.⁶⁷ It has been thought by some that the malady is now less prevalent than formerly,⁶⁸ and this opinion is apparently supported by statistics.⁶⁹ Ireland is remarkable for its small death-rate—.27 per 1,000 inhabitants—from pneumonic fever.⁷⁰

⁴⁰ Ziemssen, loc. cit.

⁴¹ Ziemssen—loc. cit.—gives the rate as 2.17 and Walton—op. cit.—as 1.80 per 1,000 inhabitants.

⁶⁹ Ziemssen, op. cit.; Sanders, op. cit.; Farr, op. cit.

⁷⁰ Ziemssen, op. cit.; Sanders—op. cit.—gives the proportion as .27 per 1,000.

France.—In this country pneumonic fever is very common,⁷¹ especially on the Alpine and Mediterranean borders,⁷² and in Paris⁷³ and some other cities.

Marseilles is particularly afflicted by this malady. The west winds—here called the mistral—sweep over the Bay of Biscay and down the valley of the Rhone, through the break in the mountains between the Pyrenees and the Maritime Alps, recur frequently during the winter, and are very blighting to animal and vegetable life. In one year, during the months of January and February, when the mistral was unusually protracted and severe, there were more than 2,000 cases of pneumonic fever—two-thirds of which were fatal—in a population of 318,000.⁷⁴

The French Army suffers comparatively little from the disease, only 3.9 per cent. of the deaths during a period of 13 years being due to it.⁷⁵ It is also rare in Havre⁷⁶ and Belle-Isle-in-the-Sea.⁷⁷

Spain and Portugal.—Pneumonic fever is rare in most parts of the peninsula,⁷⁸ although common in Lisbon,⁷⁹ Madrid,⁸⁰ and some other cities.

Italy.—This disease is extremely common in Italy,⁸¹ especially in the northern parts. It is also prevalent in the neighboring Islands.⁸²

Greece.—Pneumonic fever is rare in this country.⁸³

Africa.—In the most parts of this continent from which we have any authentic returns, pneumonic fever is very prevalent,⁸⁴ causing an annual mortality of 3.62 per 1,000 inhabitants,⁸⁵ and 9.1

⁸³ See Landerer, Arch. de Pharmacie, 1851; LaRocoe, op. cit., p. 63; Hippocrates—De Morh., Lib. ii—considered it common in his day.

⁸⁴ Cateloup, De la Pneumonie d'Afrique, Paris, 1853.

⁸⁵ Sanders, op. cit.; Ziemssen, op. cit.

per cent. of the deaths.⁷⁶ It is especially prevalent in Algiers,⁷⁷ Chamounix,⁷⁸ Constantine,⁷⁹ Arabia,⁸⁰ Capeland,⁸¹ South Africa,⁸² Senegambia,⁸³ West Coast⁸⁴ and other places, whilst it is less prevalent or rare in Egypt,⁸⁵ Abyssinia,⁸⁶ Bone,⁸⁷ Morea,⁸⁸ environs of Sahara,⁸⁹ the Eastern Coast,⁹⁰ Madeira,⁹¹ Mauritius,⁹² Azore Islands,⁹³ St. Helena,⁹⁴ St. Domingo,⁹⁵ Martinique,⁹⁶ etc.

Asia.—Pneumonic fever is not common in most parts of this continent. It is rare in Hindostan,⁹⁷ except in the northern districts,⁹⁸ Burnah,⁹⁹ Pegu,¹⁰⁰ Ceylon,¹⁰¹ the East India Islands,¹⁰² Australia,¹⁰³ etc., whilst it is common in China,¹⁰⁴ Corea,¹⁰⁵ Japan,¹⁰⁶ the South Pacific Islands,¹⁰⁷ Van Diemen's Land,¹⁰⁸ New Caledonia,¹⁰⁹ New Zea-

land,¹¹⁰ Gambier Island,¹²¹ Sandwich Islands,¹²² Riouw and Lingga Islands,¹²³ Nicobaren,¹²⁴ Ten-esserim,¹²⁵ Kamschatka,¹²⁶ Siberia,¹²⁷ Persia,¹²⁸ Turkey,¹²⁹ Syria,¹³⁰ Armenia,¹³¹ Donau,¹³² and other places.

North America.—Here pneumonic fever was common amongst the Aztecs of Mexico¹³³ and the Indian tribes roaming over the United States and Canada in past centuries,¹³⁴ and continues to prevail extensively in every part of the continent.

Arctic Basin.—Pneumonic fever has been rarely met with in Arctic expeditions¹³⁵ or in the hunting stations of the far north,¹³⁶ save in Greenland, where it is common.¹³⁷ In Alaska and the neighboring islands it does not often appear, but, when it does so, is very destructive.¹³⁸ It is very prevalent in Lower Canada,¹³⁹ the Maritime Provinces,¹⁴⁰ Maine,¹⁴¹ New Hampshire,¹⁴² Vermont,¹⁴³ Massachusetts,¹⁴⁴ Northern New York,¹⁴⁵ New York City,¹⁴⁶ Brooklyn,¹⁴⁷ Hartford,¹⁴⁸ Philadelphia,¹⁴⁹ Cleveland,¹⁵⁰ Pittsburgh,¹⁵¹ Petersburg,¹⁵² District of Columbia,¹⁵³ Cincinnati,¹⁵⁴ Indiana,¹⁵⁵

The high plateaus of Mexico afford a large amount of pneumonic fever,²¹⁹ and even the Gulf coast is considerably afflicted.²²⁰ It is rare on the west coast.

Pneumonic fever is comparatively rare in Central America,²²¹ Bermuda,²²² Jamaica,²²³ Cuba,²²⁴ the Antilles,²²⁵ St. Domingo,²²⁶ Trinidad,²²⁷ and the other West Indian Islands.²²⁸

South America.—On this continent pneumonic fever is responsible for an annual death-rate of 1.61 per 1,000 of population, and 5.8 per cent. of all deaths.²²⁹ It is rare in Panama,²³⁰ the Marañon Valley,²³¹ and a few other places, but it is common in Ecuador,²³² Guiana,²³³ Brazil,²³⁴ Peru,²³⁵ Buenos Ayres,²³⁶ Chili²³⁷ and other parts.²³⁸

REPORTS FROM HOSPITALS.

SURGICAL CLINICS AT THE WESTERN PENNSYLVANIA HOSPITAL BEFORE THE STUDENTS OF THE WESTERN PENNSYLVANIA MEDICAL COLLEGE.

BY PROFESSOR J. B. MURDOCH,

SURGEON TO THE WESTERN PENNSYLVANIA HOSPITAL AND PROFESSOR OF CLINICAL SURGERY IN THE WESTERN PENNSYLVANIA MEDICAL COLLEGE.

[Reported by WILL. N. PRINGLE, M.D., a member of the Graduating Class.]

September 29, 1888.

EXCISION OF KNEE-JOINT.

Patient, æt. 47, male, and by occupation a coal miner, has always enjoyed good health and is at present in robust condition. His parents were healthy; his father died at the age of 56 years,

and his mother is still living. Three years ago, while at his work in the mines at Mansfield, a fall of coal caught his knee, crushing it slightly, but not severely, as he kept on at his work for a month, at which time, however, his knee began to trouble him so much he was compelled to take to his bed, which he kept for three days, when he again resumed work, but only for a short time, when he was again compelled to go to bed for a few days; and so he has alternately worked and lain in bed for the past three years, until within a short time, when he became unable to work or even to stand on his leg. Upon examination I find that the mischief has so involved the joint that the articulating surfaces, cartilages, ligaments and the joint generally, has become so thoroughly disorganized as to require a surgical operation. There are two operations we may do for this man, namely: amputation of the limb or excision of the joint. The latter is a substitute for the former, and is resorted to in disease, injury and deformity of joints; and where it is applicable the mortality following it should govern us largely in attempting it. A few years ago good surgeons had almost abandoned it, so great had been the mortality following it.

Of 57 cases recorded during the late war, 44 died, 10 recovered, and 3 are unaccounted for; but since the advent of antiseptic treatment of wounds results have changed materially. I have done five excisions in the past three years, with but one death, that of a delicate child, while my friend Prof. King has done five excisions in the same length of time with no deaths. The object in view in excision of the knee-joint is different from that in the elbow, shoulder, wrist, hip, ankle or almost any other joint. In almost every other joint, we hope to get motion after excision, in the knee we do not; in fact, we make every effort to get a stiff joint, we endeavor to destroy the joint as a joint, and to that end we fix the bones solidly together with nails, destroy the synovial pouch and membranes, and hope thereby to get strength at the expense of motion.

In doing this operation we will make an incision extending from opposite the external condyle of the femur, across the centre of the patella to opposite the internal condyle of the femur, about three-fourths of the circumference of the limb, and carry the incision deeply through all the tissues down to the ligaments; we then dissect up the skin, flex the limb and remove the patella, and all the diseased tissue surrounding the joint. After this we saw a thin piece off the end of the femur and a thin piece off the end of the tibia, taking care not to remove the entire epiphysis in any case. As the normal leg is not straight, it shall be our endeavor to remove the ends of the tibia and femur in such a line to the axis of the leg, that when the two sawed surfaces are brought into position the natural bend of the leg shall be maintained. After the nails are put in

place and the drill removed, a tap or two on the head of each nail with the mallet serves to fasten them up and to draw the two surfaces into closer apposition. In addition to the nails a posterior splint will be put on, also a plaster dressing will be put on over the whole; all of which will help hold the joint immovable. Several drainage tubes having been put in, small fenestra will be cut in the plaster dressing in order that the tubes may be removed without disturbing the limb, which will be done in about one week. The dressing will not be removed for about two weeks unless pain or rise in temperature indicate that all is not doing well. The nails will be withdrawn in about three weeks, and if all goes well this man should be able to move about on crutches in about four weeks.

October 27, 1888.

We will show you first, to-day, the man on whom we excised the knee-joint just four weeks ago. You see that he is able to walk about on crutches, and you will also notice that he looks much better, physically, than he did on the day of the operation. One week ago I removed the nails, and failed to find one drop of pus in the wound, or in the track of the nails. You also see when I manipulate the limb, that the joint is firmly ankylosed, showing that complete bony union has taken place. Now, that is just the result we sought to obtain, and it is the result we have a right to expect if our operation has been properly done, and our antiseptic precautions have been properly observed. This man has been thoroughly incapacitated for work for four years, and now he has the pleasure of knowing that he will soon be able to resume his occupation, with a considerable degree of satisfaction. He is 47 years old, an age at which we should scarcely expect as favorable results as we have been able to obtain in this case. On the evening of the day of the operation, his temperature went up to 101.6° , but since that time has remained below that, much of the time being normal.

October 13, 1888.

FRACTURE OF THE SKULL.

Through the courtesy of Dr. Hyatt we are enabled to show you the case of a young man, who one week ago sustained a severe fracture of the skull. This man is 25 years old, and works in a machine shop. One week ago, while at his work, he was struck by a falling beam, receiving, as you see, this extensive stellate fracture of the skull, just over the left parietal bone. And extensive as this wound is, and considering the fact that pieces of bone were driven down into the substance of the brain, this man walked down three flights of stairs, rode to the hospital in an ambulance, and got out and walked into the ward without for a moment losing consciousness.

This fact will serve to teach you that men may receive very extensive fractures of the skull, and still retain consciousness. After this accident, Dr. Hyatt trephined the skull, removing the detached portions of bone, and elevating the depressed portions, observing through all his manipulations strict antiseptic precautions; and to-day his chart shows a temperature of 99.6° , and at no time did it exceed 99.8° . Now, this would be almost an impossible state of affairs under any other than antiseptic treatment. Under the old forms of treatment of injuries like this, we would, in all probability, by this time have this patient in an aggravated form of septic fever.

We will now remove the dressings in order to get at the drainage tube, which has now served its purpose and will be removed. This will be done as strictly antiseptically as the original operation. The skull is an exceedingly difficult location on which to do antiseptic surgery, on account of the hair, which gets very filthy. When you want to do a clean operation on the skull always shave the hair off close to the skin. Heretofore not a little trouble has been experienced in elevating the internal table of the skull, on account of its friability and proneness to break down under instruments, but my friend Prof. Brazier, of Wooster University, has invented an instrument which overcomes this difficulty. He has promised to send me one of them, which, when he does so, will be exhibited to you. The opening left here by the trephine will not be closed by a silver or glass plate, as so many people think, but will be left to nature to close, and which she will close; not by bone, but by a thick, fibrous membrane, leaving a soft spot, which will always remain over the site of the wound. In a case of this kind, not much can be done by medication. I, however, always give a cathartic, a brisk, hydragogue cathartic, which partly takes the place of the old style of bleeding. This young man has had this.

FRACTURE OF THE PATELLA.

We have here another patient, one who has a fracture of the patella. A few days ago, while trying to board a moving train, he was thrown violently against an upright signal pole, and has sustained a transverse fracture of the patella, which is a rare occurrence. Fractures of the patella may be caused by direct violence, and by muscular action, and when it is caused by direct violence, it is almost always in an oblique, vertical or stellate fracture. When it is fractured in a transverse direction, it is almost always done by muscular action, as when a person is about to fall, or be thrown down, in his violent effort to prevent his falling, and when his knee is in a semiflexed position, his patella is fractured in a transverse direction, by the violent contractions of the strong muscles of his thigh opposed by the ligamentum patella below, much the same as you would break

a stick by pulling it over your knee with a hand on either end. But in this case you see a transverse fracture caused by direct violence. This is merely an exception to the rule. This is also a complete fracture, the parts being separated from $1\frac{1}{2}$ to 2 inches, and as you see, the limb is very much swollen or puffed up by the accumulation of fluid in the joint. Now, it is very desirable that this fluid should be disposed of before we try to bring the parts together, and in order to do this, some surgeons recommend the aspirator. In this case, however, we will try milder means. First we will place a bladder filled with broken ice about the joint, and follow this with a couple of large blisters, and if this do not effect the desired result, the aspirator will then be used. Now, there are two ways of bringing the fractured ends of the patella together: first by plasters, one strip being passed around below the lower part, and strongly drawn upward and made to adhere to the skin of the thigh above the knee; another strip is passed around the upper fragment and strongly drawn down, and made to adhere below the knee. The limb must lay on its posterior aspect, and perfectly relaxed, and then, by manipulations and flexing the thigh upon the pelvis and extending the leg, the fractured ends may be brought very nearly into approximation; always remembering, however, that the upper part must be drawn down, and that the lower part cannot be drawn up, as the ligamentum patella is not elastic. The other way of reducing this fracture is to cut down on to the bone, freshen the two fractured surfaces, pass strong wires through each, draw them together, twist the wires, and so retain them in apposition until union takes place. This latter process is attended by so much danger that it is not often resorted to. Patients have lost their lives as a result of it, and many have suffered amputation. In either of these operations we can hardly hope for bony union; some surgeons claim to get bony union in favorable cases, but it has been claimed by just as good authority that bony union never takes place in these cases. The fibrous union which we do get, however, is as good for all practical purposes as bony union would be, while some claim that it is better than bony union would be, if we did get it, as the patella will never break again at the same place after fibrous union has taken place.

THE ROYAL COLLEGE OF SURGEONS AND ITS MEMBERS.—At a meeting of the Birmingham and Midland Counties Branch of the British Medical Association, the following resolution was, after an animated discussion, adopted: "That this Branch sympathizes with the desire of the Royal College of Surgeons of England to take part in the management of affairs of the College."

MEDICAL PROGRESS.

REGARDING THE RESEMBLANCE OF THE MALARIA-PARASITE TO THOSE OF FEBRIS RECURRENS.—N. A. SACHAROFF, in a preliminary communication in *Watsch.*, 1889, No. 1 (Russian), states that there exists in the blood of patients suffering from febris recurrens a hæmatazon which may be best observed immediately after the temperature begins to fall, and which then assumes enormous proportions (20 and more diameters of a red blood-corpusele). But specimens of lesser size are also found. The parasite consists of a delicate amœboid body containing a multitude of dark, round, uniform, sharply-outlined movable granules. Besides these the protoplasma contains a generally grayish, homogeneous nucleus as large as one or two red blood-corpuseles. The protoplasma sends forth pseudopodia (without granules) which sometimes separate from it and appear as small, delicate pieces of protoplasma without granules. They vary in size and are often swallowed by red blood-corpuseles in which they gradually grow and finally develop into the above-mentioned large amœboid body.

In a detailed description contained in the Minutes of the Session of the Caucas. Med. Society, in Tiflis, 1888, No. 11, Sacharoff designates the large protoplasma-lumps described by Ponfik, Ref. L. Heydenreich (Wilna), as his parasite: Hæmatazon Febridis recurrens. He declares that the granules in the protoplasma which Ponfik took for granules of fat are mostly pigment, not fat. From time to time the protoplasma itself sends forth pseudopodia, in which no granules are to be found; these pseudopodia fall off and circulate freely in the blood. By separating from the protoplasma, however, the parasites become smaller, until finally only the nucleus and a narrow zone of protoplasma containing granules remains. The nucleus itself is round, delicate, grayish, also reddish, and Sacharoff thinks that it is merely a red blood-corpusele. The nucleus sends forth pseudopodia, or buds, which separate from it and also circulate freely. Sacharoff watched such separated pseudopodia and noticed successive changes in them, *i. e.*, he saw spirochætæ-shaped threads form from nucleus-pieces within from 8 to 10 hours. They did not show any small undulations and were not very thin, but large undulations were distinctly visible. He thinks this is possibly the genesis of spirochætæ. Nor do the lumps separating from the protoplasma remain without further development. They have a motion of their own, attach themselves to red blood-corpuseles, send buds into them and finally are completely enveloped by them. Here they may assume various shapes and may grow larger and gain granules of pigment in the protoplasma.

They distend also the blood-corpusele containing them, and seem to be able to cause its disappearance. On the other hand they can emigrate with equal facility from the blood corpusele. Then the parasite becomes free and continues to grow, or decomposes as was shown above. Immediately after the crisis the three first-named forms exist in large numbers, further on during apyrexia principally or exclusively the intracellular forms are to be found. This is the main difference between it and the plasmodium malarial where the intracellular forms are found only during the fever.

This report is very important and it opens new points in the etiology of this disease. If the highly interesting discoveries of Sacharoff should be confirmed, we should have reliable means for the diagnosis of the disease during apyrexia as the intracellular forms, which can be stained with methyl blue (at least in intermittents), are easily seen. In uncolored specimens they are hard to see. The same peculiarity might then be utilized as a means of differential diagnosis from intermittents, with which febris recurrens is easily confounded.—*Centralblatt für Bakteriologie und Parasitenkunde*, Band v, No. 12.

SEMMOLA ON THE CURABILITY OF INTERSTITIAL HEPATITIS.—In a lecture on therapeutics at the University of Naples (*Il Progresso Medico*, January 15, 1889) PROFESSOR SEMMOLA exclaims strongly against the exaggerated importance which is attached to the anatomical basis of disease. He points out that the common error of associating the morbid anatomy found post-mortem in the last, and probably incurable, stage of disease with the symptoms of an earlier, and possibly curable, stage, as met with at the bedside, discourages therapeutic efforts, and leads directly to pessimist views.

So, in speaking of the curability of interstitial hepatitis, he does not refer to the atrophic stage, which is the one most commonly met with in the post-mortem room, and which is, as it were, the dregs of the disease; but to an earlier condition, when the liver is large, and the new tissue has not yet become hard, contracted, and fibrous.

Professor Semmola suggested the possibility of the curability of interstitial hepatitis in a lecture so far back as 1869. And at the International Medical Congress at Amsterdam in 1879, he details a series of cases in support of that view. More recently Dr. Millard has advocated the same proposition in *Le Progrès Médical*, and has published a series of cases in which he considers that interstitial hepatitis has been cured. Professor Semmola in his present lecture relates several further cases, but he appears to make no distinction between those of malarial origin and those due to syphilis or alcohol. It is quite possible that the former may be more readily curable than either of the latter.

It would also appear that sufficient account is not given to the establishment of a collateral circulation in the very numerous ways in which it is known to occur, and to the consequent disappearance of ascites and other symptoms, the interstitial hepatitis remaining unaltered. The reporter well remembers a middle-aged man who was tapped two or three times for very copious ascites, and whose liver was so hard and irregular that several of those who saw him thought he had malignant disease, but who lost his ascites completely and recovered sufficiently to resume his work as a railway navvy. It was difficult to attribute the result to anything but the establishment of a collateral circulation.

The principle of Professor Semmola's treatment is the rigid restriction to a milk diet. He argues that a more solid dietary, and especially meat, increases the hepatic irritation, and exaggerates the disease.—*London Medical Recorder*, March 20, 1889.

ON THE ORIGIN OF HOMOGENEOUS CASTS AND CYLINDROIDS IN THE URINE.—TORÖK and POLLACK have sought to discover the origin of homogeneous casts by clinical and pathologico-anatomical observations, as well as by histological and chemical investigations, and experiments on animals. By the results thus obtained, they join the partisans of the transudation theory, according to which homogeneous casts originate from the coagulation of an albuminous substance transuded into the renal channels directly from the blood. They consider their formation from cells or from derivatives of cells as out of the question. As chief supports for their views they cite the shape of the casts and cylindroids, and the observations which prove that these formations occur in simple disturbances of circulation, when renal epithelium is wholly normal or but slightly changed. Besides, they are formed so quickly in the kidney and in the urine that a homogeneous metamorphosis of the epithelium, or the formation and blending of vacuoli, would be impossible. The origin of cylindroids is twofold: one portion originates from the kidneys, another forms extrarenally from the secretions of the prostate, of Cowper's and Littre's glands, of the mucous glands of the bladder, of the uterus and the cervix, and differ from renal cylindroids, which they resemble morphologically, only in their insolubility in acetic acid. Against the formation of cylindroids from cells or vacuoli speaks also the circumstance that they are found alongside of almost normal epithelium and never show cross-stripes (the boundary-lines of the cells and vacuoli not yet blended). Furthermore, cylindroids occur frequently in urine, whilst vacuoli are very rare in fresh urine and in the urinary channels. Casts and cylindroids form where the quantity of the transudation is sufficient to fill completely the lumen of the urinary

channels and where it is of sufficient rigidity. Experiments especially seemed to prove the opposite. The authors regard the vacuoli, which most people think secretion products from the kidney epithelium, as cells which degenerated and subsequently swelled by absorbing liquid.

The homogeneous cast-substance plays an important part also in the formation of cell and granular casts. Concerning the question how this substance transudes, the authors believe that transudation goes on not only in the glomeruli, but also in the urinary channels. They are unable to say whether the kidney epithelium takes part in the formation of homogeneous casts or not. They likewise refrain from expressing an opinion on the factors causing coagulation, and merely mention the hypotheses advanced on this point.—*Centralblatt für Klinische Medizin*, 1889, No. 12.

THE LEUCOMAINES IN THE NORMAL BLOOD.—Under this title MR. R. WURG explains the results of careful investigations made at the instigation of Mr. A. Gantier, which have had a bearing on the question of alkaloids in the normal blood. The experiments which were made on 100 litres of ox-blood have led to the following conclusions: Normal ox-blood contains, besides the well-known bases isolated long ago, creatine, xanthine, hypoxanthine, a certain number of leucomaines, fixed or volatile, in a proportion not exceeding 3 gms. in 100 litres. The greater part of these bases were isolated in quantities too small to allow of an analysis. The form of their salts and their physiological properties are characteristic for each. Only two have been analyzed: one of them, which is volatile, is methylamine; the other, for which the name of "plasmaïne" has been proposed, is fixed; its formula is $C_5H_{13}Az_3$. The physiological action of this base is but slight, like that of most muscle leucomaines and of adenine, despite its being isomeric with hydrocyanic acid. The other bases likewise have no or but slight toxic qualities. The most poisonous among them kills a frog of average weight (15 gr.) in a dose of 2 to 3 milligrams, in about one hour. The symptoms generally observed were a slowing of the heart and of the respiration, and an increase in the sensitiveness of the muscles. In Guinea pigs no physiological effects could be observed. The elimination of these fixed bases occurs probably through the kidneys, whilst methylamine is eliminated by the lungs. Although the proportion of these leucomaines in the normal blood is very small, their presence is nevertheless of interest, in the matter of the elimination of nitrogen.—*Les Nouveaux Remèdes*, Vol. v, No. 6.

A CASE OF FATAL TETANUS DURING ENLARGEMENT OF THE STOMACH.—MR. BEURMANN has had opportunity to observe a case in which a pa-

tient died within a few hours from tetanus which extended to the respiratory muscles. This patient had been suffering for a long time with a considerable enlargement of the stomach, and had passed, a few days before, through another crisis characterized by vertigo, torpor, and a pricking sensation in the limbs. These symptoms, which introduced the fatal crisis, are very common in enlargement of the stomach, and should immediately attract the physician's attention.

Analogous cases are not rare; there are no less than fifteen known to medical science. The first one was published by Kussmaul. Of these fifteen cases eight were followed by death. This justifies the presumption that tetanus originating in the stomach is extremely dangerous. Its extreme gravity, as also its tendency to affect the respiratory muscles, prevents its being taken for common tetanus. Apropos of the latter, it ought no longer to be considered an entity, but rather as a complication which may occur under various conditions and circumstances.

As regards the pathogeny of the spasm in enlargement of the stomach, several theories have been advanced. According to Kussmaul, it is due to a concentration of the blood; according to other authors it is of reflex origin; M. Bouchard ascribes it to a self-intoxication. I favor this last view, although I have had no opportunity as yet to verify it. Mr. Hayem observed a case of enlargement of the stomach in which two successive attacks of spasms occurred. The patient died subsequently from a sort of cholera morbus. Mr. Hayem thinks it possible that the fatal cases mentioned by Beurmann resulted from a displacement of the viscera.—*La Semaine Médicale*, Vol. ix, No. 13.

ETIOLOGY AND ORIGIN OF ACUTE PERITONITIS.—PRIVAT-DOCENT A. D. PAWLOWSKI, of St. Petersburg, has made, in the laboratories of J. Rosenbach, Göttingen, and of Pasteur, Paris, a number of experiments, with the following results:

The first series of experiments with the injection of chemical substances into the peritoneum showed that the different substances (croton oil, trypsin, cold filtrates of pathogenic microbes) produce an aseptic hæmorrhagic peritonitis, with the exception of the cold filtrates of erysipelas cocci which was without reaction.

The second series with microbes showed that even large quantities of non-pathogenic microbes do not affect the peritoneum, whilst a small number of pathogenic microbes, among them the staphylococcus aureus, produces fatal acute peritonitis in rabbits, and the longer the animals lived the more evident became the purulent character of the inflammation. The bacillus pyo-cyanus, which is considered harmless by many, proved pathogenic when injected into the peritoneum.

In the third series of experiments with unfiltered, filtered and sterilized digestive secretions, it appeared that only the first produced peritonitis which is caused by especially short bacilli isolated in pure cultures.

The fourth series of experiments showed that indifferent foreign bodies which can envelop and retain microbes, as also irritated or inflamed conditions of the peritoneum favor, under the influence of chemical substances, the development of acute peritonitis.—*Internationale Klinische Rundschau*, March 17, 1889.

THERAPY OF BASEDOW'S DISEASE.—PROFESSOR EULENBURG, of Berlin, speaking on the therapy of this disease, considers it best to place patients in a sanitarium for nervous diseases. Often the most brilliant results are obtained, even in far advanced cases, in establishments and sanitariums located in high altitudes. Even the worst complications with organic heart-disease, valve troubles, incompensation, do not present an absolute contra-indication to a sojourn in high altitudes as is generally supposed. In some cases few such altitudes are not well borne, rapid circulation, difficulty in respiration, etc., ensuing. In these cases lower altitudes and sub-alpine climates are preferable.

This climatological treatment is aided by the simultaneous use of balneo-therapeutic, diatetic, and electro-therapeutic measures. Regarding the first Eulenburg recommends the lighter forms of cold-water treatment and carbonic-acid baths, and lukewarm carbonic-acid and brine baths of a short duration on the other.

As concerns the diatetic measures the Playfair or Weir-Mitchell cure, milk and kumyss cures should be used as in other neurasthenias (for as such Eulenburg regards Basedow's disease).

As to electricity, a mode of treatment especially developed by Eulenburg, hydro-electric baths are to be used. Eulenburg prefers monopolar cathode baths. With this general electrization a local application of electricity may be combined, either after the method of Romain Vigouroux, or after the method of Eulenburg, who in many recent cases tension—or rather influence—electricity, especially in the form of franklinization on the head (head douche) and the positive point current directed upon the heart. (*Berl. Klin. Wochenschrift*, No. 2 and 3, 1889.)—*Internat. Klin. Rundsch.*

ON THE INDICATIONS FOR LAPAROTOMY IN ACUTE PROCESSES.—GERSUNG, in the *Wiener Med. Presse*, 1888, No. 46, collects all those cases under the name of "acute," in which danger of a suddenly fatal termination compels the physician to decide immediately whether a laparotomy should be made, or whether other remedies are to be used which place less responsibility upon the

physician, and endeavors to decide at what moment safety can be expected only from operation, or how long it may be deferred without depriving the patient of this last possibility of a cure.

Laparotomy should be performed for injuries to large vessels or to organs of the abdominal cavity containing many blood-vessels; traumatic, or in very rare cases spontaneous rupture of liver or spleen; rupture of the foetal sac in tubular pregnancy; dangerous vomiting of blood, and perhaps also a bleeding carcinoma of the stomach. As to peritonitis laparotomy is of value chiefly as a preventive operation; in general peritonitis already existing the prospect of success is very limited.

Laparotomy is indicated whenever the abdominal cavity is opened in order to prevent septic processes, and in perforation (also traumatic) of intestines, rupture of an abscess and flow of pus into the peritoneal cavity, rupture of the bladder, impacted gall-stones, obstructions in the intestines, whether caused by invagination or valvulus, by strictures resulting from scars or new formations, by obstruction from an internal hernia, or by foreign bodies that entered into the intestinal channel from outside, or by a gall-stone remaining in the intestine, by sloughing of a portion of an intestine as a result of inflammatory processes, or by inherited malformation.—*Centralblatt für Gynäkologie*, 1889, No. 12.

SULFONAL FOR NIGHT-SWEATS.—Although the number of remedies recommended for night-sweats is very large, it may not be amiss to give some information regarding a new cure: Sulfonal, the soporific recently so warmly recommended. Bättrich's attention was first attracted to the subject by the case of a lady 80 years old, to whom he had administered only $\frac{1}{4}$ gram as a soporific. The lady had been suffering with night sweats so profuse that her clothes were changed twice every night. After taking this powder, she asked him whether he had mixed anything for those sweats in it. Further experiments showed that in most cases night-sweats could be prevented by $\frac{1}{2}$ gm. of sulfonal. He considered the effect of sulfonal to that of atropin, but it is wholly free from unfavorable side-effects. Moreover its effect is lasting, the sweats of the second night being much less profuse without sulfonal.—*Therapeutische Monatshefte*, March, 1889.

PICROTOXIN, AN ANTIDOTE OF MORPHIUM.—PROFESSOR ÁRPÁD BÓKAI, of Klausenburg, considers picrotoxin the most rational antidote for morphia. The two substances act in opposite ways upon the respiration-centre of the medulla oblongata, morphia paralyzing it whilst picrotoxin increases its activity. In cases of poisoning by morphia, picrotoxin is actually life-preserving, as it checks the paralysis of respiration

and prevents the decrease of the blood-pressure by strong irritation of the vasomotor centre, producing vascular contraction. The opposite effects of the two substances upon the cerebrum is of no importance in poisoning. It must be remembered that the only antidote for morphia known so far—atropin—cannot be given in large doses. Bókai is of the opinion that picrotoxin could be used also as a prophylactic in chloroform-narcosis, to prevent asphyxiation. He promises further reports on the subject.—*Therapeutische Monatshefte*, March, 1889.

REGARDING A NEW BLOOD TEST IN COAL-GAS POISONING.—K. KATAGAMA says this test consists of the addition to blood containing coal-gas of orange-colored ammonium sulphide and acetic acid, which produces a beautiful light-red color, whilst normal blood turns greenish-gray or reddish or greenish-gray. The test may be best made as follows: Dilute 1 ccm. of the blood to be tested with 50 ccm. of water, pour 10 ccm. of this into a test-tube, and add first 0.2 ccm. of orange-colored ammonium sulphide and 0.2–0.3 ccm. of 30 per cent. acetic acid, and turn the test-tube upside down two or three times. Blood impregnated with illuminating gas diluted from 1:5 to 1:7 showed distinctly the characteristic color with the test reagents, whilst the spectroscope proved ineffective with a dilution of 1:4, and Hoppe-Seyler's soda test with a dilution of 1:5. *Centralblatt für Klinische Medizin*, 1889, No. 12.

CAMPHORATED NAPHTHOL.—This mixture is composed of one part of naphthol and two parts of camphor, triturated together *dry*. Désesquelles discovered that naphthol liquefies in camphor, and M. Bouchard has shown the considerable antiseptic power of naphthol, and its great advantage of being non-toxic. He advises the use of camphorated naphthol as a topical antiseptic, having used it with success in many cases of excoriations, wounds, and ulcerations, and in diphtheria as an application to the throat.—*Journal de Médecine de Paris*, No. 7, 1889.

PERNICIOUS VOMITING WITH AND WITHOUT PREGNANCY.—DR. LEVY, in a treatise published by Heuser, Berlin, describes in detail a case of continual vomiting during pregnancy, and reviews a number of other authors on the ætiology and therapeutics of the subject. In the case mentioned the vomiting was a result of anæmia of the brain and ceased after proper treatment of the latter trouble. Another patient was not pregnant; the vomiting originated in a uterine disease, and ceased after the latter was cured.—*Correspondenz-Blatt für Schweizer Aerzte*, March 15, 1889.

SATURDAY, APRIL 27, 1889.

LEGISLATIVE BODIES AND SCHOOLS OF
MEDICINE.

The various Bills or propositions brought before the Legislatures of many of the States, intended for regulating the practice of medicine, form a curious variety and strikingly illustrate the vagaries that still possess the popular mind concerning the nature and extent of medical science and art. A large part of these vagaries arise from the erroneous use of the phrase "Schools of Medicine," and the remainder originate from the confusion of ideas about personal rights. In past centuries, before the natural sciences had been developed into well-defined departments of science founded on carefully observed facts, analyzed and classified; before chemistry had enabled its votaries to resolve almost all bodies into their elementary constituents and determine the relations of each to every other; and before the scalpel of the anatomist had separated the various structures of the human body from each other and enabled the physiologist to study the relations and uses of every part, human knowledge consisted in part of empirical rules concerning the affairs of everyday life and labor, and in much greater part of fanciful theories and speculative dogmas under the name of *philosophy*. In those times each master mind with more boldness and skill in inventing hypotheses and plausible theories than the common mass, drew around him admiring followers, and he became the founder of a sect or so-called school of philosophy. Hence history informs us of the Schools of Aristotle, of Plato,

etc., with their parallels in medicine, as the School of Hippocrates, of Galen, of Cullen, of Boerhaave, of Darwin and Brown; or the School of the humoralists and the School of the solidists. It was thus that the phrases, Schools of Philosophy and Schools of Medicine, used to designate the theoretical dogmas of some bold and skilful leader of human thought, became incorporated into all departments of literature and have been handed down to our time. But with the development of chemistry, organic and inorganic, analyzing and recombining all the materials within human reach, came also the discovery and application of physical laws and forces to the advancement of all the arts and industries of man. Of necessity, the observation, collation and classification of facts, aided by experiments, rapidly superseded and rendered obsolete the dreams and speculative dogmas that had constituted the "Schools of Philosophy" of the past ages, and gave instead our present scientific knowledge of the vegetable and animal kingdoms of nature, and of the inorganic matter with the laws and forces that govern it, under the comprehensive word physics. Under the same influences and in the same parallels of time medicine underwent the same changes. The practical study of human anatomy, the analytical study of all its parts, the discovery of the circulation of the blood, the complex functions of the nervous system, the chemical changes in digestion, assimilation and nutrition, and the counter-changes in disintegration and elimination, soon rendered every previous so-called "School of Medicine" obsolete, by giving us in their place the well developed sciences of anatomy, physiology, and organic chemistry. A knowledge of these branches quickly compelled the recognition of the fact that diseases or morbid actions were only deviations in some direction from the natural functions or structures, and hence the sciences of pathology and therapeutics followed, and with them, *pari passu*, the arts of surgery, practical medicine, and hygiene or sanitation, became as truly departments of science as are physics, botany, natural history and geology. Therefore it is as absurd, at this day, to designate the aggregate branches of medicine as a "School of Medicine," as it is to speak of a School of Mathematics or a School of Natural History. And yet newspaper writers, members of legislative bodies, and even many members of the profession and prominent medical journalists,

continue to speak and write of the "regular School of Medicine" on the same plane as the little bundle of fanciful dogmas they call the Homœopathic School, the Eclectic School, the Christian Science School, the Electro-physio-pathic School, etc.; and it is very rare that any form of law having any bearing on the education or practice of medical men, or on the protection of the public health, is proposed in one of our State legislative bodies that is not marred by some recognition of the various so-called Schools of Medicine.

As examples, a Bill was recently introduced into the Legislature of Pennsylvania providing for the appointment of a State Board of Medical Examiners by the Governor, subject to the approval of the Senate, making no mention of Schools of Medicine in any way, thereby leaving the appointing power untrammelled. But it was speedily so amended that no one school of medicine could have a majority in the Board. So in the Michigan Legislature an Act is pending for a State Board to be composed of two members from the regular, the homœopathic and the eclectic schools of medicine.

Has not the time come when the members of the medical profession should cease to call themselves a "School of Medicine;" and refuse to respond to such designation when used by others? Legislative bodies have the right to *protect* the *people* by enacting such laws as will require every person proposing to practice medicine and surgery to possess a good knowledge of medical science and art, but with medical sects and theories they have properly nothing to do.

MICROBES IN HEALTHY FEMALE ORGANS OF GENERATION.

The presence of various microorganisms in the vagina when in an apparently healthy condition has been noted by several observers. Recently, DR. G. WINTER has been prosecuting a more systematic and extensive investigation, regarding the presence or absence of these bodies in all parts of the female sexual organs when in good health.¹ In the vagina, a variety of microbes were always present, and in considerable numbers. In the os and cervical canal he found a similar variety generally present but not always. He found their number much increased during preg-

nancy. But he states positively that he found no microorganisms of any kind, either in the cavity of the uterus or in the Fallopian tubes. According to Dr. Winter's observations the most numerous variety of microbes present in the healthy vagina and cervical canal, is the staphylococcus, identical with the pathogenous cocci. If his observations on this point are correct, it affords additional evidence that pathogenic germs are harmless so long as they are in contact with naught but healthy living tissues, and become actively disease-producing only when in contact with degenerate or necrotic structure or the products of the same. Again, if these pathogenic germs are always present in the vagina and cervical canal, and increase during pregnancy, it only requires the presence of disintegrating blood or placental débris in the lochial discharge, or even the presence of an atmosphere containing an excess of albuminoid ammonia, to furnish the microbic papulum needed for bringing the puerperal infection into its usual destructive activity. And inasmuch as the lochial discharge always contains more or less blood for several days after confinement, it would seem that every case of labor leaves the woman with all the elements necessary for a possible puerperal infection, present, without reference to what might be communicated by the physician, midwife or nurse. Possibly, however, Dr. Winter may be mistaken in the opinion that the microbes he found in healthy genital tracts were really pathogenic; and other observers may be more fortunate in finding some healthy vaginas free from microbes.

THE MEETING AT NEWPORT.

The Fortieth Annual Meeting of the Association, which is to convene at Newport, R. I., on the 25th of June, promises to be one of unusual interest. The preliminary programme is published in THE JOURNAL, under date of April 13th. It shows that the Committee of Arrangements already has its work well in hand. From the known efficiency of this Committee we are confident that every reasonable effort will be made to render the meeting in all respects a notable success.

We are happy to state also that the officers in the various Sections are actively engaged in securing such papers for presentation as shall command

¹ Zeitschrift für Geburtshülfe und Gynäkologie

the interest of those who attend, and elicit such discussions as time will permit. This is well. The best thought of the profession should be represented there—and those who make sacrifices for the purpose of attending should be amply repaid for the effort.

The assembling of prominent medical men from all sections of our country is pleasurable and profitable. The social gatherings of the profession at these annual meetings are always delightful. But we wish to emphasize the fact that the Association has a vastly more important mission to fulfill than that of simply bringing medical men together for mere social enjoyments.

Its value to the profession and to the people of this commonwealth lies not in its power for the culture of social amenities—pleasurable as that may be—but in the value of the work done, in the several Sections while the Association is in session. Its real mission is, and must be, the promotion of medical progress and the advancement of the healing art. To this end the papers there presented should represent the best efforts of our ablest men, and the same order of talent and culture should be enlisted in their discussion. To this end special care should be had in the selection of the officers of the Sections. And these officers when they accept their responsible positions should do their work so wisely and so well that the programmes when presented to the profession should possess the power to draw all interested men unto them. This manifest need for the future welfare of the Association, we believe, will be largely met at Newport.

RUPTURE OF THE INTESTINE.

At the regular meeting of the Chicago Medical Society, April 15, 1889, DR. J. J. ALDERSON presented a section of the small intestine that had been ruptured under the following circumstances. The patient from whom it had been taken was an adult laboring man, wearing a truss for the support of an inguinal hernia. While engaged in some work a loop of intestine was forced out by the pad of the truss. He succeeded in returning it back into the abdominal cavity, but it was immediately followed by acute pain and the rapid development of all the symptoms of peritonitis, terminating early in death. The post-mortem examination revealed much serous fluid freely

mixed with fecal matter in the peritoneal cavity, extensive peritonitis with some patches of plastic lymph or pseudo membrane, and a liberal opening through the coats of the section of small intestine exhibited to the Society. Dr. Alderson stated that he had been unable to find any case on record of an intestinal rupture under similar circumstances, and thought the accident one of very rare occurrence.

EDITORIAL NOTES.

SUNSTROKE EARLY IN THE SEASON.—At Pittsburgh, Pa., on April 19, 1889, the temperature was reported to have reached 82° F., and John Jenkins, a steel worker, and an unknown man on Smithfield street, were stricken down with "sunstroke."

DR. W. F. WILSON, a specialist in the department of ophthalmology, practicing in Denver, Col., died on April 19, 1889, from an overdose of morphine to produce sleep. He had been troubled with insomnia, and was only 29 years of age at the time of his death.

SOCIETY PROCEEDINGS.

Gynecological Society of Boston.

190th Regular Meeting, February 14, 1889.

THE PRESIDENT, W. SYMINGTON BROWN, M.D.,
IN THE CHAIR.

The report of the Treasurer for 1888, showing a balance of \$404.59, was read and accepted.

PATHOLOGICAL SPECIMENS.

DR. A. L. NORRIS exhibited a placenta with an unusually short funis (nine and a half inches). The patient, Mrs. J. D., married, has a distorted pelvis and has always been delivered with much difficulty by forceps and ether. She has been delivered by me of living children as follows:

February 2, 1887, a male child, weighing 10½ pounds.

February 20, 1888, a female child, weighing 9 pounds.

February 14, 1889, a female child, weighing 9 pounds.

Thus, in the interval of two years and twelve days, have I delivered this patient at term of three living children.

DR. J. COLLINS WARREN, by invitation, read a paper on

THE DIAGNOSIS AND TREATMENT OF CANCER
OF THE BREAST,

to which the Society listened with marked attention and interest. Dr. Warren alluded to the great changes which have recently taken place in the treatment of this formidable disease, investing it with a new interest to the surgeon. Whereas the old operation contemplated a removal of the mammary gland, with a portion of the integument and a shelling out of the glands in the axilla when enlarged; the methods advocated in England, Germany, and this country now, contemplate a removal of the gland and its coverings; the fascia of the pectoralis muscle and a complete dissection of the fat and glands from the axilla and the lower margin of the pectoralis, and it is known as the "completed operation."

This operation has recently been objected to by able surgeons, and indeed, all operative interference has been thought useless, since it is claimed that life is as long in the average of a large number of cases not operated upon, as in those which have been subjected to operation. Moreover, the complete operation has been said to increase the mortality 50 per cent.

The reader dwelt on the importance, in the first place, of an early diagnosis particularly in

Dr. Warren then gave some statistics bearing upon the mortality of the completed operation, and stated that he had had thirty-one consecutive cases without a death. Gross gives fifty-three cases of his own and his colleagues with two deaths. It is fair to assume that the antiseptic methods are daily becoming more familiar to the average surgeon, and are constantly being improved upon; and in the light of recent experience, it is not too much to hope that a mortality of only 3 per cent. could be obtained. Dr. Warren was unable to give an account of all his cases; but he quoted examples taken from his tables showing an immunity of three years and a half after operation; of four years and of four years and a half without recurrence at the present time. He is in favor of a dissection of the axilla even in cases where there are no glands to be felt; for in one of the cases quoted, glands were found in the pyramidal mass of fat removed from the axilla. He thinks that it is probable that when the statistics of the next few years are rolled up and counted, we shall find that surgery has succeeded in accomplishing a cure in 20 per cent. of the cases.

DR. J. F. FRISBIE: Does Dr. Warren believe the case of Mrs. P. to which he referred, was the result of the blow on the breast?

those doubtful cases which are those usually submitted to the surgeon for a decisive opinion. He showed an instrument, devised by Dr. S. J. Mixer for removing powder grains from the skin, which he had adapted to this purpose. It consists of a canula with a sharp edge which can be bored into the new growth, and, by withdrawing a short distance and then advancing in a slightly different direction, a cylindrical mass is cut off, which can be removed in the canula. In this way good sized sections can be procured, by which a satisfactory microscopic examination can be made, and the nature of the growth determined.

This can be done in the doctor's office with the aid of a subcutaneous injection of cocaine. A small puncture through the skin with a narrow bistoury facilitates the introduction of the instrument. Antiseptic precautions prevent subsequent inflammation, and no trouble had occurred in any of the cases operated upon by him in this way. This is an old method which had been abandoned, but can now be revived and made practical by the advantages offered by antiseptics and improved microscopical technic.

DR. WARREN: I am inclined to the opinion that the blow was the cause of the cancer which developed in her breast.

DR. FRISBIE: Then you believe cancer may follow injury as a result of that injury alone?

DR. WARREN: Yes. There are cases where no other reason can be given.

DR. JOHN C. IRISH: I have been much interested in the instructive and practical paper that has just been presented. The ingenious device, by which Dr. Warren secures a portion of the morbid growth for microscopical examination, is very valuable; for it will give great aid in the early diagnosis of tumors of the breast, that is, as to their malignant or non-malignant character. With women of middle or advanced age, every solid growth in the breast is so liable to contain cancerous elements or to acquire them, even if it is benign at first, that my rule of action is, to advise their immediate removal. If the disease is malignant, its early removal is of unquestioned advantage; if benign, this treatment by excision is not inappropriate. One very important matter that Dr. Warren presents to us for discussion is the question, Whether in all cases of extirpation

of the breast for cancer or supposed cancer, we should make the completed operation, so-called, which consists of as thorough a removal as possible of all the fat and glands in the axillary space? Whenever the latter are appreciably affected, there can be no question as to the necessity of the completed operation. But when there is no apparent disease in the axilla, is there sufficient reason for converting a simple surgical operation into a severe and formidable one? I believe not, for the following reasons:

First. In a large proportion of cases the completed operation will permanently cripple the corresponding arm and hand, that is, the patient to a greater or less degree is forever incapacitated, from performing work.

Secondly. Since it is impossible to remove all the glands of the axilla by an operation that is continued only a reasonable length of time, we have left a nidus for the reappearance of the cancer; and I do not see any reason why a portion of the glands may not afford just as good a one as the whole of them. Therefore, we would logically infer that the completed operation must be a failure in its attempt to prevent or even retard a recurrence of the disease.

Thirdly. The cases of permanent recovery that have followed excision of the breast have been examples of the incomplete operation for the most part. None of these cases could have done better if they had had the completed operation, and most of them would have done much worse; for most of them would have been permanently crippled instead of completely cured.

Dr. Hodges, last fall, published in the *Boston Medical and Surgical Journal*, an article in which he gave the statistics of a large number of excisions of the breast alone, (that is, in which the incomplete operation was made) and in which the cancerous disease afterwards reappeared either in the scar or elsewhere. Among these cases the secondary malignant growths recurred first in the axilla in only 3 per cent. Now, if these statistics of Dr. Hodges are reliable, and no one, so far as I know, has questioned their correctness, in one hundred cases of excision of the breast alone, the cancer will return in only three cases in the axilla first. Now, are we justified in submitting these one hundred cases to that formidable surgical procedure, "the completed operation," instead of the simple excision of the breast, when by so doing we shall kill ten of them, and harm or cripple many of the remainder, when we have only the hope of curing or benefiting three? Could a surgical operation with weaker legs stand upon, logically speaking, be proposed?

DR. A. P. CLARKE said that he had for a long time held to the view that cancer is a local instead of a constitutional disease, and since accepting that view he had been accustomed to advise that an operation for the removal of a cancerous breast

be done with the least possible delay. By means of the microscope an early diagnosis can be made, and much valuable time saved instead of being lost, as it formerly was, when it was deemed necessary to wait until the disease had become so well pronounced that but little hope for recovery after an operation had been decided upon, could be entertained.

He was much pleased with the little instrument, devised by Dr. Mixter and shown by Dr. Warren, for the removal of a small section of the growth, before its excision, for purposes of microscopic examination. He agreed with the reader that all the affected glands in the axilla and vicinity should be removed, however extended the incision has to be carried in order to accomplish this. This method he had followed in his own practice for some years, and he well remembers having been called to assist Dr. Marcy in his first case about twenty years ago. At that time the method of removing the affected glands of the axilla was hardly known or practiced in this country; but the results obtained by Dr. Marcy, as well as by the speaker, showed that quite a large number of the cases operated upon, made a permanent recovery. In regard to the impairment of the arm occasionally resulting, as has been mentioned, this should not be regarded as an objection to the operation, as those results occurred in the earlier cases when the glands were removed, and subsequent experience has taught us how to preserve more of the nerve branches that pass through the axillary space and to the arm, injury to which caused the untoward result. There is another class of cases that sometimes occurs, not mentioned by the reader, in which, after operation for removal of a cancerous breast and affected glands of the axilla, though there is no recurrence of the disease at the former site of the operation, there is a development of cancerous disease at a distant part or in a neighboring organ. In one case occurring in Dr. Clarke's practice, that of Mrs. L., æt. 45 years, he removed on November 19, 1880, the left breast and affected glands of the axilla on account of cancer. The patient recovered, and enjoyed good health for five years, when she began to show signs of cancerous cachexia. After much severe suffering, she died November 18, 1886. The autopsy showed there were extensive deposits of cancerous matter in the liver. The disease appeared in the form of whitish spots of circular shape and of various sizes. These spots also, at first view, had the appearance of ulcers, but on closer inspection, were found to be firm and smooth, and each was depressed slightly in the centre. On section, they were noticed to be hard or schirrous, and yellowish in appearance. Some of the deposits were much harder than others, having the appearance of age, while others were of quite recent date. Some were an

inch in diameter; others of the size of millet seeds. The right kidney contained a few recent deposits similar to those in the liver. There was no appearance whatever of any return of the disease at the original site. The question that is of interest is, was the occurrence of the disease in the liver due to infection derived from the breast before the operation? The extreme hardness of some of the cancerous deposits indicated great age. The speaker believed that if he had been called at an earlier date to excise the breast, the patient would have escaped further infection. Other cases of a somewhat similar history the speaker had seen, but they tended to show that cancer of the breast is a local, instead of a constitutional disease, and therefore, we are justified in resorting to excision of the cancerous breast at the earliest possible date. He would like to hear Dr. Warren's explanation of the secondary deposits in the liver.

DR. WARREN: Secondary deposits in the liver may come about by possible extension of the original disease into the substance of the pectoralis muscle; thence it may go to the thorax, and then we may have a cancerous pleurisy. If an internal depot is once established, a new metastasis in different directions may occur.

DR. F. L. BURT remarked that the difference of opinion of authorities has its influence on other men who are not authorities. Both the time and extent of the operation are of importance. Dr. B. has seen recurrence of the cancer on the line of the cicatrix. He believes that the majority of cases which need any operation require the completed operation. The *American System of Gynecology* has an article by Dr. Gross in which there are pictured wounds, both open and closed. Possibly this makes no difference in the recurrence. He has seen some operations where a great amount of skin was removed, but the wound was closed and the patients went home in three weeks. Of thirty-five cases, the later ones went home in eighteen days, and the healing was by first intention, which is very different compared with several months when the wound is left open. He has seen two cases of recurrence. One recurred in a year and a half, and the other recurred in four weeks in the skin.

DR. MARY E. BATES asked Dr. Warren if, on general principles, he would remove a growth the size of a hen's egg?

DR. WARREN: Some growths of that size have been found to be cystic on exploration, and the fluid ran out through the canula and all then collapsed. It is a good rule to use the exploring canula in doubtful cases.

DR. S. J. MIXTER: The punch spoken of by Dr. Warren was devised by me to fill a want Dr. Warren noticed and had mentioned to me, namely: something that should take the place, in solid tumors, of the aspirator in tumors with fluid con-

tents. Instruments were long ago invented for tearing shreds of tissue from tumors and organs situated beneath the surface of the body, the best form being a very small pair of forceps that could be introduced through a trocar, canula or aspirator needle. These, however, gave but small shreds, which were not large enough for sections, and were unsatisfactory for examination in every way. The instrument shown is simply a steel tube, which may be of any convenient size, fitted with a cylindrical needle and sharpened at the end by being bevelled from the inside, the edge being at right angles to the axis of the tube. By making a puncture through the skin with a tenotome and introducing the punch through the opening, it is made to cut its way as far as necessary by rotation with slight pressure. The tube is then withdrawn about a quarter of an inch, the point turned to one side, and again advanced and rotated, thus cutting off the lower end of the cylinder. The finger being placed over the upper end of the tube, it is then withdrawn, when the piece of tissue is pushed out of the tube by a plunger. In this manner any solid tumor that could safely be reached by the aspirating needle can be examined. The pain of the operation is slight, and may be relieved by a deep injection of cocaine. I have examined in this manner tumors of the breast, tongue, face, antrum, uterus, deep-seated tumors of the neck, etc.

It has been stated that dissection of the axilla is not called for, as it cannot be complete in any case, as the region above and behind the axillary vessels and nerves cannot be reached. Of course, when the disease extends from the axilla in every direction, as in advanced cases, a thorough dissection cannot be made. But I have found by injection of the lymphatics from the breast, that the course of the vessels and chain of glands is over the edge of the pectoralis major close to the muscle, and then toward the apex of the axilla, *below and in front of the vessels and nerves*. Unless the disease in the axilla is far advanced, we find no glands above them. As another objection to the completed operation, it has been stated that the arm must necessarily be disabled. By observing the rule laid down by Küster that the subscapular nerves be saved, and by preventing the gluing of the arm to the side by the cicatrix, these difficulties may be overcome. By careful dissection the nerves may easily be saved, and by stitching the skin high up in the axilla by a quilted suture to one of the upper serrations of the serratus magnus, in the manner that I have described elsewhere, there need be no cicatricial contraction. By making the incision so that the line of suture of the breast wound is vertical, and prolonging this incision, not along the middle of the axilla, but *above* the axilla high up on the pectoralis muscle, the final line of sutures, when the arm is at the side, is in full view in front. By the use

of this method in a considerable number of cases. I have been able to give a useful arm and one that could be easily raised above the head, even in cases where it has been necessary to remove a large part of the pectoralis major, and where a large surface was left to heal by granulation.

DR. HENRY O. MARCY stated that he had listened to the paper of Dr. Warren with exceptional interest, not alone on account of its scientific merit and practical instruction, but because it marked a departure almost revolutionary from the teaching which had dominated the surgical thought of Boston, particularly as representative of the views emanating from the Massachusetts General Hospital.

Twenty years ago it had been his good fortune to be the pupil of the late Dr. Bennett, of Edinburgh, who strongly held to the opinion that cancer was first a local and not a constitutional disease. Convinced of the correctness of these views, Dr. Marcy proceeded at once to put into practical execution the legitimate deduction, that if cancer is a local disease its treatment should be prompt and thorough as possible in its eradication to be effective. This led him very early to the careful dissection of the axillary glands and all suspicious and superfluous fatty tissue, and it has been his custom in all cases to dissect carefully the axillary space. Although it cannot be doubted that such radical measures add materially to the gravity and difficulty of the operation, especially as done before the days of carefully applied aseptic surgery, in his own experience he recalled but two cases during all these years where the operation had resulted fatally. This good result, however, he ascribed in large measure to his early adoption of Listerism, and its application in all its painstaking details. He recalled one of his first cases, operated on in 1871, where he removed a cancerous mammary gland of the right side from a young, fleshy, and otherwise healthy woman. This was not alone true cancer as judged by himself, but the opinion was confirmed by Dr. Fitz, since Professor of Pathology. In the primary operation the axilla bore no evidence of disease and therefore was not opened. Three months later, however, the axillary space was filled with a mass of enlarged glands, which he dissected out very thoroughly, quite after the manner described by Dr. Warren. He had the satisfaction a few months since of examining this patient. She has remained in good health without the slightest impairment or discomfort in the use of the arm. More than ten years since Dr. Marcy sent a poor woman, a coatmaker, to the Massachusetts General Hospital, for the removal of cancer of the right breast, where the glands of the axilla were also affected. She was refused admission, because of the advanced stage of the disease rendering, in the judgment of the surgeons in charge, the operation ill-advised. Assisted by

his friend Dr. T. H. Burchard, of New York City, at that time his guest, they made the dissection complete. Although he has twice since removed recurrent glands, when seen quite recently she was still earning a livelihood with her needle. At the Hospital Dr. Marcy recently removed recurrent cancerous glands from a patient from whom he had removed a cancerous breast six years ago. In the primary operation he was assisted by Dr. W. H. Baker. During these years she had had no discomfort. Although these illustrative cases are the exception, they stand for a class of accepted cures and teach the advantage of early radical treatment. Dr. Marcy was assured that Dr. Warren had given expression to the opinions of a large class of modern surgeons, which views he was glad to believe would early be accepted by both physician and patient as a decided advance in the surgical treatment of this most dread disease. He heartily congratulated Dr. Warren upon his distinctive satisfactory results.

DR. G. W. JONES asked Dr. Warren if it is dangerous to leave any fat.

DR. WARREN: The cases differ. Some are seen with little or no fat, and sometimes there are layers of fat and tissue. This it is important to remove as much as possible. Dr. Warren referred to a case of cancer of the tongue, that had been on the iodide of potash treatment for syphilis and did not get well. With the canula the diagnosis of cancer was made, and the operation was performed immediately. In abdominal tumors, Dr. W. has used the largest-sized aspirating needle with suction for the purpose of exploration. In a case of kidney disease we generally get only blood, but if the material in the needle is carefully examined with the microscope enough tissue may be found for a diagnosis.

DR. S. N. NELSON testified to the advantage to both patient and surgeon from the possibility of accurate diagnosis of new growths before operation. Formerly it was necessary to wait until after removal before the specimen could be examined by an expert and the verdict rendered. In the sister profession an attempt is made to determine the *necessity* for punishment before it is inflicted. Should not we do the same? The ingenious instrument invented by Dr. Mixer opens a new era, rendering this possible. By the use of this simple device we are enabled to procure our specimen before operation and without injury to the patient, and subsequent procedure can be determined upon at leisure. This, it seems to me, is the greatest gain to the patient in the possibility of obtaining proper treatment. This gain may well be compared to the advantage which the higher powers of the microscope give us over the examination of the gross specimen; for it enables us to utilize these high powers at the time when their testimony is most needed.

Dr. Nelson himself has been accustomed to

make microscopic examinations of the cervix uteri in suspected cases, after etherization of the patient. A small piece is readily snipped off with the scissors. It is put at once upon the freezing microtome and sections are made, which, stained in alum carmine, render possible an opinion, if not a positive diagnosis, in five minutes from the time of procuring the bit of tissue, the patient continuing in the state of anæsthesia; and then the necessary operation is at once performed. If however, the expert with his laboratory facilities cannot be present at the operation, or if more time is desired for making the diagnosis, the small bit of cervical tissue can be obtained with the aid of cocaine, and, after diagnosis, the operation can be performed subsequently under ether. But I think a better specimen can be obtained for examination by Dr. Mixer's device than by the scissors, even where it is possible to use them. A great advantage in Dr. Mixer's instrument, as it seems to me, and one not mentioned by any of the speakers, is that by its use there is obtained a specimen which may be a sample of the whole new growth, even including normal healthy tissue. Thus we get not only the centre, where the pathological changes are the greatest, but also toward the edges where they are less marked, and even the advancing borders themselves; and thus the invasion of the healthy tissue can be studied. Of this every microscopist knows the advantage.

In illustrating the use of the instrument, Dr. Warren had brought a breast which he had amputated that morning, in which the diagnosis of cancer had been established by its aid. The site of entrance of the canula a few days previously showed as a small red spot. The cylindrical specimen removed was about $1\frac{1}{4}$ inches long and $\frac{1}{8}$ inch thick. One-half of it divided longitudinally was exhibited. From the other half sections had been cut both longitudinally and transversely, and these, with others, were exhibited by

DR. WM. F. WHITNEY, who called attention to them, as showing what good topographical sections could be obtained from these exploratory punchings. In view of the more extended operation now performed in cases of malignant disease, he said it was now more than ever essential that the surgeon should know exactly the nature of the growth with which he had to deal. And with the aid of the instrument shown by Dr. Warren he was able to judge what he would be called upon to do before he touched his knife.

ELECTRICITY FOR ASCERTAINING THE TRUE NORTH.—The *Electrician* reports a rumor from Berlin to the effect that a means has been discovered of using electricity for ascertaining the true north, instead of the magnetic needle; that in short, the new means will be superior to the compass and is likely to supersede it.

Obstetrical Society of Philadelphia.

Thursday, March 7, 1889.

THEOPHILUS PARVIN, M.D., IN THE CHAIR.

DR. J. M. DA COSTA reported a

DOUBLE UTERUS AND VAGINA.

Uterus normal in length, with thin walls and antelexed; otherwise well shaped, but with septum of from $\frac{1}{16}$ to $\frac{1}{8}$ inch thick, running from the tincæ to fundus, dividing it into two equal parts. Both sides of uterus were open, and a sound could be easily introduced into either side. Septum perfect in its entire length.

Vagina on first inspection appeared like a single one, but closer examination showed a septum reaching from the vulva to within less than $\frac{1}{2}$ inch of the uterus, attached to and tying together the front and back walls of the vagina. Septum was thick and fleshy near vulva, thin near uterus. Opening on left side of vagina was good but small; that on right side not to be seen at first, but could be found by hooking the finger around the cervical end of septum and working it down, when the end could be seen at the vulvar opening. Septum was cut and raw edges stitched together. Before operation the septum was about $2\frac{3}{4}$ inches long; after cutting and suturing the parts contracted to about $1\frac{3}{4}$ inch long, and the vagina, which before operating would with difficulty admit the very smallest speculum, bore easily the largest-sized "Nengebauer" blades. March 6. The severe pelvic pains she continually suffered from have all disappeared. Menses formerly were a mere discoloration, lasting twelve to twenty-four hours; she is to-day just over a good full menstruation, which lasted over four days.

DR. J. M. BALDY read a paper entitled
COMPLICATIONS FOLLOWING ABDOMINAL SECTION.

The attention of surgeons, in the past and at present, has so commonly and almost exclusively been called to the perfection of the different abdominal operations, that sight is lost of the possible complications which may follow; or if noticed at all, they are kept locked up in the bosom of the individual himself, and the profession at large hears and consequently knows very little about these annoying, and at times serious results. In consequence of this, medical men are continually running across these patients and are having their faith in the value of the original operation shaken. Most men go into an operating room, see the operation, have a pathological specimen shown them, and then go away, satisfied as to the justifiability of the operation and confident as to the results. They may or they may not see the patient several times during the treatment, but are generally satisfied with an inquiry as to how the patient is progressing, and finally have the satisfaction of

hearing that she is well and has been discharged. The case is probably reported as cured in some society or medical journal, and thus the favorable statistics are swelled, and inexperienced and untrained men are led into attempting the operation, usually with the result of sacrificing several lives before they are frightened off.

It is about time for surgeons to look at and seriously study some of the dark sides of abdominal surgery; for a dark side it certainly has. Our results, as far as removing disease is concerned, are about perfected; let us now turn some of our energies into preventing or alleviating some of the after complications which are in many cases as bad as the original disease itself; probably not causing such immediate danger to life, but producing symptoms just as hard to bear, as far as the patient is concerned, and practically, to her belief, fully as bad, at times, as her former trouble.

When I first began to turn my attention particularly to gynecological surgery, especially the abdominal variety, I was considerably worried that my cases did not always run as smooth and uncomplicated a course as I had been led to believe those in the hands of my friends and others did. That they were not perfectly well when they got up, and came to me sometimes for weeks, complaining of one thing or another, was a source of great mortification to myself. And finally I began to find that troubles continued and others appeared which it was extremely difficult to control. At first, supposing that I was the only one so afflicted, I thought there must be something radically wrong, either with my operations or with my handling of the case afterward; and yet I could not reconcile these thoughts with the fact that I usually had the very best of assistance at the operation, and the constant advice of most competent men in the conduct of the after-treatment. Now I am constantly seeing and hearing of cases with similar troubles as my own, and some with complications I have never personally met with. These cases are by no means confined to the practice of any one man or any class of men, but represent patients of nearly every prominent operator in this city. Nor do I think that these results are confined to Philadelphia, but will be found wherever abdominal surgery is practiced.

To fully consider the causes, prevention and cure of these complications, is beyond the scope of this paper; my object being simply to call general attention to the prevalence of their existence and to make a few remarks on the most frequent of them. Some of the subjects have been, from time to time, noted by other surgeons, and have been called to the attention of the profession, only to be dropped almost as if they were subjects not to be handled and publicly discussed. Among the most frequent of these might be mentioned hernias; simple fistula tracts; fecal fistulas; pain, pelvic or abdominal; edema of the lower extrem-

ities. I have seen many patients suffering from all of these troubles, and have had some of them follow in my own practice.

Holmes has found that he had 30 per cent. of hernias following his operations. Now, as these cases were for the most part hospital patients, he could certainly not have kept track of them all, and so, if the whole truth were known, the per cent. would be much higher. It would seem, at first sight, that a patient developing a ventral hernia would return for treatment; but not so, for in my own case, with the exception of one patient, none of them ever reported, and I only discovered their existence from outside information. Thirty per cent. is, I think, a fair average of hernias following section. Most of the operators with whose work I am familiar have, I am confident, almost if not quite that proportion. I know of many cases in this city, of which the operator himself is not yet cognizant. Now, a ventral hernia is by no means a harmless thing. I can recall women who suffer almost as much from the presence of the hernias as they did from the original disease; in fact, more so. One case I know of had originally a small, unadherent ovarian cyst, found in the course of a general examination, and which gave her few or no discomforts. She now has a good-sized ventral hernia, from which she suffers considerably. These hernias constantly tend to increase in size, and where the woman is one who must be on her feet constantly, carrying heavy burdens, lifting heavy weights, or in fact doing anything which will increase the tension at the abdominal opening, the result must invariably be a rapid enlargement of the protrusion, with all the accompanying distresses. There is no good reason that some of these cases should not eventually, from various causes, become strangulated, and require a second and more serious operation; this has actually occurred. The mere protrusion and displacement has caused so much trouble, that an operation has been devised for the closure of the opening. The causes of hernia have been somewhat a matter of discussion; some contending that the drainage tube is most at fault, while the advocates of the tube repudiate that idea. Then again, improper suturing is charged with the results. Whatever the cause, the lesion is certainly a lack of union of the muscular tissues and the deep fasciæ; the remedy is plainly that of securing perfect apposition of the edges of these tissues. Time is frequently, in an operation, a most important element, and there is no need of wasting it by passing a separate row of sutures in the peritoneum itself, as has been advocated and practiced in some of our neighboring cities. The peritoneum always unites, and does so in a very short time. As far as I know, it has never failed to do so, excepting in those cases where the whole incision failed. The hernia is always found to have a covering of skin, superficial fascia and perito-

neum. It seems to me that a continuous catgut suture of the muscles and deep fasciæ is all that is needed, beyond the usual all the way through suture. I can recall a case where the presence of a hernia, by demanding an operation for its closure, resulted in the death of the woman.

This city now contains a large number of women with fistulous tracts in their abdomens. Some of them have followed drainage, and others have been produced by abscesses rupturing through the incision, and the track never closing again. The extraperitoneal method of treating the pedicle in hysterectomy is a very frequent cause. The length of time it takes the clamp to come away is often so great as to leave an opening, which constantly discharges pus, in small quantities, it is true, but yet enough to be exceedingly annoying and uncomfortable. I have had two such fistulæ following hysterectomy, and neither of them have I yet been able to cure; one, however, now gives fair promise of soon closing. I have, fortunately, had no other fistula tracts following my operations. One case I know of was a few years ago operated on for some pelvic trouble, and after a few weeks the patient was sent to her home with a drainage tube (rubber, I think), in her abdomen. The surgeon lost sight of her, and the tube, being neglected, became most foul. The case afterwards drifted into one of our large general hospitals and there died. Another case was operated on for a pus tube. The second tube and ovary, being apparently healthy, were left *in situ*, but these afterwards took on disease and a second operation failed to remove it. A third operation was undertaken by another surgeon, with what result was never known but by a select few: certain it is that a fistula track followed, after a severe illness. This woman also finally found her way into one of the general hospitals, and was miserable enough to die, if she did not do so; what finally became of her I do not know. A third case had one side of a double tubal trouble removed, and the drainage track never closed. I saw this woman a year or more after the operation, on her deathbed. The track was discharging pus freely and always had done so. Before her death feces were also finding their way through the opening, a slough having evidently come away from the bowel. A fourth case, after everything else had been done without success, had a counter-opening made into the vagina by another surgeon into whose hands she had fallen. The operation also, unfortunately, opened the bladder, so high up that it was impossible to repair it. She has now a vesico-vaginal fistula in addition to her other troubles, and at last report was in a dying condition. And so I could go on with case after case, some as bad and some not so bad; but, at its best, a fistula is a most miserable complication, and too much attention cannot be given to their prevention. If the drainage-tube is not responsi-

ble for the herniæ, it certainly is for a large number of the fistulæ; and although I am a firm believer in the advantages to be derived from free drainage, I fully realize its disadvantages, and often wonder if it could not be done away with oftener than it is. The great preventive of the formation of these fistulæ is to prevent abscesses forming and the necessity of their subsequent discharge, if they do form, it is better to go boldly in and empty them at once, than to wait and have them open by a slow, tedious and uncertain process, which may not be brought to an end before the patient is; the avoidance of the unnecessary use of the drainage tube and, when it is used, the most careful attention to its cleanliness, and its early withdrawal. I believe a permanent track results oftener from an unnecessarily prolonged use of the tube than from any other cause.

Fæcal fistulæ are not so common, and yet enough of them occur from time to time to be a warning of the danger of their production. When they do occur, they are usually so deeply seated and so bound around by inflammatory products that they cannot be reached, and if they are reached, as a rule, require one of the most dangerous and difficult operations in the whole range of abdominal surgery. I can recall a number of these accidents. One could not be reached after an extended trial, and the whole incision was closed up in order that the patient might die as quietly as possible; this she did not do, however, but lived in spite of everything, and the track afterward closed of its own accord. Another case required the most constant and careful irrigation, after an unsuccessful attempt had been made to reach it, to save the woman's life. And so they go; if an attempt is made to close them, a great risk is taken; if they are let alone and do not close spontaneously, the patient had better be dead. The usual cause, as far as I have been able to observe, is intestinal adhesions to diseased organs. Often after tearing a loop of gut loose, I have returned it in fear and trembling, lest a piece at the point of adhesion slough out and give me a fecal fistula. The prevention is the greatest care in tearing loose each adhesion, and a most careful attention to the after-treatment. When they do occur, they are best left alone.

The continuance of pain or the appearance of a pain not before present, following abdominal section, is so common, that every one engaged in this kind of surgery must have noted its frequency. This pain is usually not very severe, but is of a constant nagging character, such a one as to so constantly wear on a woman's nervous system that it soon renders life a misery to herself and a burden to every one around her. At times, however, it assumes a severe character and becomes almost unbearable. I have known of a large number of such cases, some of which required an operation for their relief. In two cases

of this kind the only lesion found was an adherent omentum to the abdominal incision, the freeing of which cured the pain. Many others are now going about, suffering as much as they did before the operation. Most of this pain is, I believe, due to adhesions formed between the omentum or intestines and raw surfaces left by the operation, and the subsequent dragging on these points. This would seem to be true, as most of the cases which I have known of and which were operated on and the adhesions released, have been cured or nearly so. I also think that the adhesions in the original disease often cause most of the suffering; this is especially so in the pelvic cases. From these same adhesions we have sometimes an obstruction of the bowels, either at once, or later after convalescence, and causing death in consequence. I can remember several cases of this kind which could be explained in no other way; and, in fact, some of which were demonstrated to be so by a post-mortem examination. The remedy for their formation and all their attendant dangers and discomforts is to keep the bowels moving, so they can have no chance of adhering. The best way of accomplishing this is by purgatives, and by the non-use of opium. Fortunately, the indications for purgatives are so many and so constantly present, that they can almost always be used.

Œdema of the lower extremities I have a number of times seen; sometimes only temporary, but at others of long enough duration and severity to be of considerable annoyance to both patient and surgeon. In my own practice this has occurred several times, but has always eventually cleared up.

When every person about to undergo an abdominal operation must run the gauntlet of all these complications, as well as many more unmentioned, it becomes a serious matter in deciding for or against an operation. We have here more than the immediate risks to life to consider; we must think, if the patient has his or her present disease removed, will she be any better off, or may she not be the worse for the interference? At any rate, such a state of affairs should be a warning to inexperienced men not to be misled by the brilliant reports seen in the journals, and not to rush thoughtlessly into an operation, expecting to produce the same perfect results. They should know that, as a rule, only favorable cases are reported, and that men do not like to publish to the world their bad work or misfortunes. Abdominal surgery is by no means the simple, easy procedure some men would make us believe, and such an operation should never be undertaken except after the most careful consideration of all the risks that must be run, the chances of benefit to the patient, and in the presence of actual demonstrable disease. Until the dark sides of abdominal work are well known to the profession at large, the *furor operations* which have been so justly complained

of will continue, and many women will succumb to the results of inexperience. He has had cases of fistula where the drainage tube was not used, but these were due to non-encapsulation of the pedicle ligatures. In one, while using the syringe, the ligature was washed out. This gave him the cue, so in the others he fished the ligature out by means of a small hook on the end of a fine wire. On the other hand, in the case of an ovarian abscess, he had kept drainage up for several months, and yet the track closed. It is his intention in a third case to pass nitric acid to the bottom of the fistula and see what can be accomplished in this way. In this case she menstruates through the track. He thought if operators would wait some time after they have operated, before reporting their cases, they would find a number of hernias. He takes a good deal of pains to avoid this accident and close the abdominal wound in an analogous way to that described by Dr. Price. The tendon, when retracted, he brings forward as much as possible with forceps, so as to bring it in contact with its fellow. He has had cases, in spite of every care. In the official report of Imlach's cases, although these were all cases of oöphorectomy, needing a very short incision, the percentage of hernias was 15. He keeps his patients in bed for two weeks before allowing them to sit up. In two cases in which he removed the ovaries, in fibroid tumors, he has had the incision rupture from too early taking out of the stitches. In these cases he sometimes leaves them in for two weeks. One case went home nineteen days after operation, in spite of orders, and the train becoming derailed, the jarring forced the cutaneous part of the wound open. Stitches had to be put in.

DR. M. PRICE did not think with Dr. Baldy that abdominal surgery had anything to regret in these cases. He admitted that much of the dirt and filth, and many of the accidents which follow these terrible operations, are actually due to the surgeon. He did not wonder at there being fistulous tracks, for the reason that in many of these cases the adhesion to the bowel are of such strength that their separation often removes everything down to the mucous coat. He has seen as much as six or seven sutures applied to such a case. Fistula is a repetition of the old abscess, which finds its way to the surface through the drainage track. All of the disease has not been removed. In many cases the fistula saves the woman's life, and gives the surgeon a path through which to perfect his otherwise imperfect work. Fistula is a proof that the case has not been properly cared for. He did not believe that 30 per cent., or even 5 per cent., represented the number of hernias. He has only seen two cases follow. Their closure is untended with danger. If due care and cleanliness are observed fistulae will not occur.

DR. WM. GOODELL wholly agreed with the writer of the paper in regard to the stubborn nature of these fistulae, and to the impossibility of avoiding them. He had now three cases of fistula. One had followed the removal of an intra-ligamentary cyst, in which he had reopened the wound for bleeding. She recovered, but a faecal fistula had made its appearance about the fifth day, and had never closed. He had to peel off the tumor from the rectum. It was now a year and a half since the operation, and she was in the hands of a competent surgeon in the country. The only annoyance to the patient is an escape of gas from the wound. The second case, followed, the prolonged use of the drainage tube, after abdominal section, for pelvic abscess. He had not had charge of the after-treatment, but she was in the hands of a skillful surgeon. It may be needless yet to make a counter opening in the vagina. The third case was one of recurrent, intra-ligamentary cyst. The fistula resulted from a previous operation in which the surgeon used the clamp many years ago. He operated last November, and removed a recurrent cyst lying in a very large abscess cavity. A drainage tube was then used, which he still kept in because he could not get the fistula to heal from the bottom. To-day he made an application of iodine to the tract and told the husband to repeat it daily for a time.

DR. J. PRICE was a little surprised that one so deeply interested as Dr. Baldy was in this subject of abdominal surgery, should stimulate vicious elements to criticism of our present position, especially since they now had their attention turned towards surgery of the brain, spinal cord, etc. Dr. B. speaks of hernia. The position of the incision, the condition of the abdominal walls and the manner of introducing the sutures are of great importance. Death has followed tight sutures, and he was satisfied that herniae often followed them. He always draws his sutures lightly. If you used three or four to the inch, tied them lightly, with perfect coaptation, your results will, as a rule, be perfect. In introducing his sutures he takes in half as much skin as fascia and twice as much fascia as peritoneum. This gives better apposition to the centre of the wound. He has not had a suture track abscess for more than a month, nor has there been any mischief about the tube. Nursing is of the greatest importance. The old nurses are meddlesome and dangerous, and he was glad to see them replaced by younger women. The tube can be dispensed with very often if the irrigation be thorough. Most surgeons are in too much of a hurry to get their patients up. Early rising is dangerous, and he has known surgeons to brag of getting their patients home in ten days. In fistulous tracks through which menstruation occurs, the only thing to do is to tie the tube and

release it from the abdominal incision. He was often led to deliver the bowel, in order to release adhesions and even then torn the bowel down to the mucous coat. This does no harm if the serous surfaces are brought together. A drainage tube resting against those torn bowel surfaces favor the occurrence of a fistula. A man who gets scared at a fistula or ventral hernia is not prepared to do good work; his work begins in doubt and ends in disaster. The operation for curing a ventral hernia is not dangerous. We cannot ignore the importance of precision in diagnosis. We must try to decide as to the probable nature of the lesion. Dr. Baldy called attention to one point, that is the necessity of recognizing something definite, on which to operate. Savage and others are satisfied to operate for subjective symptoms only. This is not right.

The other day he refused to operate in a case which had multiple abscess in the lungs. Two weeks before he had gone to the house prepared to operate, but the family had refused. The time will come when operators will be most arbitrary in these cases. We shall have the right to say, that if the general practitioner waits until the eleventh hour, we will not step in, only when it takes a feather to depress the beam. Last summer a patient refused operation, to-day she sent for me and requested it. Peritonitis is often due to an imperfect toilet. It is often of limited extent or localized, leaving adhesions to portions of the viscera. This is a common source of pain and discomfort. The only good remedy is to do the work over and release the adhesions. This past summer he had either done himself or assisted others do eight of these operations over, and they had been the most difficult and trying of his whole experience. He wished to call attention to one case on which he had operated three times. Dr. Baldy saw the work. When he first saw her pus was escaping from the umbilicus. He opened the abdomen but failed to remove anything. Drainage was followed by a good recovery, but the wounds did not close. A year later he reoperated, but a fistulous track was left. Again a year later he used a catheter made of coils of wire. He passed this along around the ileo-pectineal line, towards the region of the kidney. He dissected along the pelvic bones and irrigated through the catheter. Last week, she was delivered of a fine baby, somewhere in the west. In this case he could find the ovaries and there was no lesion of them or the tubes. This is the only case of pelvic abscess without tubal disease, he had ever seen, in a long and rich experience. He wished to speak of two of the cases referred to by Dr. Baldy in his paper. One case he had operated on early in his experience, and had removed only one side of a specific tubal trouble. This he would never do again. The patient went into other hands and he did not

care to refer to the ghastly surgery which followed. Another case of which he had personal knowledge, was a case of imperfect surgery. This was a large pus sac which could have been removed, but was drained. The woman died of psoas abscess. Skene had called attention in his book, that pelvic abscess frequently caused spoas abscess. The incomplete removal of diseased tubes, should be rectified. If an inch of tube is left it will most likely do mischief. He has curetted into the cavity of the uterus, removing a cone-shaped piece. The tubes should be tied hard on to the uterus, and the ovaries should be tied at a good surgical neck, and the results will be about perfect.

(To be concluded.)

FOREIGN CORRESPONDENCE.

LETTER FROM LONDON.

(FROM OUR OWN CORRESPONDENT.)

Scheme for Providing Ambulances for the Metropolis—Color Blindness and Color Perception—Causes leading to Outbreaks of Measles in Glasgow—Glycerine Enemata in Obstinate Cases of Dysentery in young Children—Tobacco Smoke as an Antiseptic—Influence of Electric Light upon the Eyes.

Mr. Ryan recently read a paper at the Middlesex Hospital before the Hospitals Association, which gave the outlines of a scheme which will be a great boon to Londoners. Dr. Livingstone is said to have remarked that the ordinary wayfarer in the streets of London stands in more danger of injury to life and limb than a traveler in the wilds of Africa. What is now wanted is a number of proper ambulances scattered all over the metropolitan area, so that in case of accident one shall always be obtainable. Mr. Ryan's paper set forth the details of a scheme which has been elaborated with this object. Briefly, the plan is to raise a fund of £1,500 for the purchase of seventy Ashford litters, in addition to those already kept at police stations and certain hospitals, and to distribute them at a number of new stations within the four-mile radius. Mr. Ryan suggested that the Fire Brigade stations would be good centres. But still other posts would be required, and there, it is suggested, might be certain railway stations and public buildings. It was announced that there would be no difficulty about the £1,500 required for the initial outlay. What is wanted is the collection of a guarantee fund to cover the cost of generally keeping up the undertaking. The annual expense is estimated at £277. The scheme, it is announced, will soon be an accomplished fact.

Dr. Eldridge Green, in a paper upon *Color Blindness and Color Perception*, held that the color

perception centre of every individual was able to appreciate a certain number of units of color, these units corresponding more or less to the bands of the solar spectrum. Dr. Green considers the average number of units to be six, namely: red, orange, blue, yellow, green and violet, but persons of unusually good color perception passed a seventh, viz.: indigo or dark blue, which was placed between the blue and the violet. In persons with color perception below the average, one or more units of color would be wanting. He considered that orange was the first to disappear, and it was replaced by a widening of the red and yellow bands. Such a person belonged to the five unit class. The blue band disappeared next, the violet then extending to the normal blue green junction. The next band to fail was the yellow, the red then reaching to the green. The green and red then became as one band, and so the units were reduced to two, the violet still remaining. In total color blindness these two were replaced by a neutral band. Dr. Green deduced the following facts as to color perceptions in his investigations: 1. A person can have no conception of a color which does not form one of his psycho-physical color units, or a very apparent modification of one of them. 2. If the colors belonging to two adjacent units be mixed, an impression of both units is obtained which is plainly perceived as a mixture. 3. If two colors not adjacent be mixed the intermediate color will tend to be brought before the mind, or white will be the result in the case of pure light, gray where there is partial absorption. 4. If any number of colors be mixed, the resulting impression will be that of a unit, a modified unit or white.

Dr. Russell, Medical Officer of Health for Glasgow, has published some rather startling statistics tending to show that an outbreak of measles in his district was due to infection during attendance in church. During the month of January forty-two persons belonging to the congregation of a Gaelic church were taken ill with measles. Taking twelve to fourteen days as the recognized period of incubation, Dr. Russell connects two serious groups of cases with the attendance at the church of two girls, on December 30 and January 13 respectively. One of these girls, it is ascertained, had come from an infected house, while the other had actually taken the disease two days before. Two other girls who usually worshipped elsewhere, but were in this particular church on the 13th, became ill on the 26th, and other circumstances pointing in the same direction are noted. Dr. Russell considers that unless something like perfect isolation and disinfection can be guaranteed to a person who is suffering from infectious disease in a house, all healthy members of the household should be debarred from attendance at school, church, or other place of concourse.

Lately Dr. George Rice has found that the gly-

cerine enema is one of the very best and most reliable means of combating the obstinate dysentery in young children which is frequently most difficult to relieve. Simple diarrhœa, too, quickly yields to the glycerine treatment, a couple of drachms being, according to Dr. Rice, generally sufficient to ensure some improvement, which a second dose completes. In place, however, of enemata of the ordinary kind, Dr. Grewcock recommends a tuft of cotton wool soaked with glycerine and applied in the same manner as a suppository, a few minutes sufficing to bring about the desired result.

Tobacco fumes have often been stated to be antiseptic. More than once it has been said that smoking has protected a house from small-pox, and even from cholera. Quite recently Dr. Hajek, of Vienna, has declared that smokers are less liable to diphtheria than non-smokers in the ratio of 1 to 2.8, and Dr. Schiff says that smoking is forbidden in the bacteriological laboratories, because it is known to hinder the development of bacteria in the various culture media.

A communication has been made by a well-known oculist of Cronstadt concerning the bad influence of the electric light upon the eyes. There have come under his observation within the past ten years thirty people suffering from a disease of the eyes. The symptoms were the same in each case, and all the patients had perforce of their employment been accustomed to remain for hours at a time near electric lighting apparatus. The new disease is called photo-electric ophthalmia. The patient is apt to be wakened in the night by great pains around the orbits, accompanied with an outpouring of tears. Intense photophobia is another characteristic of the malady.

A parcel was during this month discovered by the porter of the Huddersfield Infirmary, and on being opened it was found to contain 225 sovereigns. This is the second gift presented to the institution in this strange manner, a sum of £284 having been left at the Infirmary a few years ago.

Miss Flavin, a young lady from Liverpool, is on her way to Father Damien's leper colony. Brave, earnest woman; she knows that she is about to doom herself to a repulsive life among pariahs whose only business is to await a loathsome death. "I am," she said to a friend recently, "not seeking notoriety or reward, only the spiritual comfort of doing for these dying creatures what their terrible disease keeps other people from doing."

Dr. J. W. Washburn has been appointed to take charge of the new department of bacteriology at Guy's Hospital. Sir William Jenner is reported to be still far from well. It is understood that in the event of his resigning his office at court he will most probably be succeeded by Dr. Russell Reynolds, who is now physician to the household.

G. O. M.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

Meeting of the New York Academy of Medicine—Paper by Dr. T. Gaillard Thomas, on Mania and Melancholia following Gynecological Operations—Six Cases reported.

One of the largest audiences of the season assembled at the first meeting of the Academy of Medicine, in April, to hear a paper by Dr. T. Gaillard Thomas on *Acute Mania and Melancholia or Sequelæ of Gynecological Operations*. The object of the paper, he said, was to place on record what he thought must be a rather remarkable experience as regards the matters in question. He desired to call attention at the outset to the fact that he did not announce these peculiar and alarming states as complications, or necessarily as results of operative procedure, but merely as sequels, which might or might not, be dependent upon it. Further, in this connection, he wished to disclaim the position that the operations performed for the relief of diseases peculiar to women are especially liable to such sequences; although all his personal experience was limited to this particular field.

Having defined his idea of the conditions entitled acute mania and acute melancholia, he stated that he would relate six illustrative cases. Out of these, he said, four were violent, and showed great mental exaltation throughout, while two were melancholic in their development; but they were acutely, violently melancholic, bustling about wringing their hands in their very distress, and after a short illness they died, as did two of the four who presented symptoms of pure exaltation.

Case 1.—Mary M., æt. 21, single, by occupation a cook, had noticed during the year before she was seen an abdominal enlargement which had steadily and rapidly increased. She had emaciated very rapidly, and was at the time she came under observation extremely weak and low spirited, and now felt that unless relieved very soon she would die from exhaustion. Physical examination revealed a large accumulation of fluid in the peritoneum, and, in addition, a round tumor occupying the whole of the left side of the abdomen. Although the case was not looked upon as a favorable one for operation, it was determined that, since extirpation of the tumor offered the only chance for the saving of life, it should be resorted to. The operation was accordingly performed, and the patient rallied well after it. She was fed upon liquid diet, and quieted by the administration of opium. Nothing existed to excite alarm, except her extreme nervous depression, and with the exception of this symptom

she appeared to be progressing favorably until the seventh night. Then she seemed more than usually nervous and excitable, and desired to see the priest, who was accordingly sent for. On visiting her early on the morning of the eighth day Dr. Thomas found that a great change had come over the patient during the night. Her eyes were wild and haggard, her face maniacal, her tongue red and dry, and she constantly talked in an incoherent and violent manner, like a woman suffering from puerperal mania. As he entered the room she covered her face with the bed-clothes and screamed out that he had leagued with the priest to murder her. Her pulse was now 160, and she remained in the same maniacal state until evening, when she sunk into coma and died. No post-mortem could be obtained.

At the time of this patient's death, now exactly twenty years ago, he regarded the condition which destroyed her life as one of acute septicæmia, a pathological factor which was then only just coming into notice, and one of which almost nothing was known. His subsequent experience with septicæmia, however, had convinced him that he was in error in this hypothesis. This case was by far the most rapid that he has ever met with. Its acute stage could not have lasted more than thirty-six or forty hours, while its prodromic, or melancholic, stage had existed ever since the operation. It was in all probability that mental state which made the patient constantly persist, as she did, in the assertion that her death was certain. An examination of the membranes of the brain, he thought, would have been most interesting in this case if an autopsy could have been obtained.

Case 2.—Mrs. X., a wealthy and fashionable lady, came under his care on account of severe suffering at her menstrual periods. She was 35 years of age, the mother of four children, and a stout, well-made woman. Her health was perfectly good, except that as her menstrual periods approached she would begin to suffer such intolerable neuralgic pain in the region of the ovaries that her life was rendered wretched. After consultation with two of the most eminent general practitioners of the city, the ovaries were removed. She recovered rapidly from the operation, but at the end of three weeks a low grade of melancholia developed, which soon took the form of violent acute mania, marked by tendency to strike her attendants. Her violence rendered it necessary to remove her to a lunatic asylum, and here she remained for four or five months, entirely insane. She then recovered and returned to her home and after the lapse of six or eight years is still perfectly well.

Case 3.—A Jewess, multipara, æt. 35 years, entered Dr. Thomas's service at the Woman's Hospital, and was submitted to the operation of perineorrhaphy. There was nothing peculiar in

this operation as to severity or any other feature, and after it she did perfectly well until the ninth day, when the sutures were removed. At that time she became violently maniacal; talking constantly, jumping out of bed, throwing her arms about, and berating her attendants in strong, though not absolutely improper, language. It proved so utterly impossible to control her that a straight-jacket had to be applied. The patient raved violently for four days, and then sank into a comatose condition and died.

Case 4.—Mrs. R., a multipara, æt. 42 years, who for years suffered from retroflexion of the uterus, which was marked by profuse menstruation, came to him from Liverpool, England, for the repair of a badly lacerated cervix. The operation was performed at his private hospital, and presented no peculiar features. The patient's manner was noticed to be somewhat odd, and after the removal of the sutures, on the ninth day, she told him that in a few days she wanted to have a private conversation with him about a terrible crime which she had committed some years before, and the memory of which had ever since filled her with remorse. Two weeks after the operation the patient left the hospital; but after remaining away for a fortnight she was brought back suffering from acute melancholia. She was constantly depressed on account of remorse for a supposed crime, would sit silent for hours, and would then get up and pace the room slowly and solemnly, wringing her hands, weeping, and bemoaning her sad lot. She continued in this state, in the meanwhile gradually growing weaker, for ten days, when she became comatose and died. Uncontrollable insomnia was one of the most marked features of the case.

Case 5.—Mrs. C., a multipara, æt. 65 years, was submitted by Dr. Thomas in his private hospital to amputation of the breast. Even before the operation she seemed to be a flighty and eccentric person, but after it all her symptoms were intensified. On the ninth day the sutures were removed, and from this date the patient became gradually depressed, was sure that she could not recover, and wept almost constantly. She suffered during the earlier part of her illness from insomnia, and continued to do so until the symptoms of coma began to show themselves. The state of acute melancholia advanced until she refused all nourishment, and for a time she was sustained entirely by rectal alimentation. This patient lived for about two weeks after the breaking out of the attack, and then slowly passed into coma and died. Towards the close of the case the urine became albuminous and presented hyaline casts.

Case 6.—Mrs. M., a widow over 60 years of age, who had in early life borne several children, entered his private hospital to have a cancerous breast removed. Even before the operation her

somewhat peculiar manner excited attention, but it was not suspected that she suffered from any real mental aberration. About a week after the operation she began to grow noisy and irritable, and by the ninth day, when the sutures were removed, she was at times, chiefly during the night, absolutely maniacal. Then periods of perfect calm and lucidity of intellect would occur, and last for hours. At the end of three weeks from the time of operation, partly in consequence of her earnest desire, partly because it was thought a change of scene would benefit her, she was allowed to return home. Here in a few days violent mania developed, and at the present time she is still insane.

Having concluded his narration of cases, Dr. Thomas stated that there was very little literature extant upon this subject, which, until recently, had attracted no attention. Prior to the year 1887 there was nothing. During that year Dr. Edward J. Ill, of Newark, N. J., published an interesting pamphlet entitled "Acute Psychoses following Gynecological Operations," which embodied his own experience and that of some German physicians. In it he collated the records of ten cases in which acute mental aberration followed gynecological operations. Of these three occurred in his own practice. The first was a case of acute mania following ovariectomy, the second one of melancholia following ovariectomy, and the third was one of melancholia following a minor operation upon the bladder. All recovered. The reports of the seven cases which followed are all drawn forth by the discussion excited by a paper read by Graube before the Berlin Gynecological Society, in 1887. One case reported by Graube occurred after perineorrhaphy, performed by Paul Ruge, and was entitled, by the reporter, a case of hypochondriasis. The second case was reported by Durelius as following amputation of the cervix. Czempin reported five cases of acute insanity which occurred at Dr. H. Martin's hospital. Of these, two followed excision of the rectum for carcinoma, one, an operation for prolapse of the uterus, one, an excision of hæmorrhoids, and one, an ovariectomy, which ended fatally on the tenth day; the mania being the cause of death. In the same year Guanck reported a case of severe melancholia following simple perineorrhaphy.

In 1888 Werth, of Kiel, read a paper on this subject before the German Gynecological Society, at Halle, in which he stated that in 300 operations on the female genital tract, he had in six instances observed psychical disturbances, due to the operation. In two cases the operation was total extirpation of the ovaries; in two, removal of the ovaries, and in two, ovariectomy. One patient was violently excited before the operation. In five cases the mental disturbance took the form of melancholia, and in one, of mania. In one case the psychosis appeared five days after

operation, in one, eight days after, and in one, three weeks after; while in the remaining two cases it developed after the patients had been discharged. Of the six cases, three recovered, one after fifteen days, one after four months, and one after eight months. In two of the other cases there was no improvement, and the third patient committed suicide three and one-half months after the operation. The result could not be referred to iodoform poisoning, as the drug was used sparingly or not at all. Sanger, in discussing this paper, said that he recalled several cases in which cerebral symptoms had developed after gynecological operations. In two instances these were clearly referable to iodoform; though little was used on the dressings. In spite of the facts stated, however, he believed that patients with pelvic troubles having a tendency to psychosis should be treated in the same manner as other women.

In an article by Fillebroun, of Hamburg, published in the *American Journal of Obstetrics* for January, 1889, the author mentioned three cases of mental disturbance following gynecological operations observed by Prochowick, of that place. In two cases of melancholia improvement was very slow, while in the third case, which was one of violent mania developing three months after operation, the patient entirely recovered.

Dr. Thomas then went on to say that in four out of his six cases there was evidence of eccentricity even before operation, and in two of these four it was quite marked at times. In all the cases except one there were distinct prodromic symptoms following operation, and antedating by some days the formal outburst. In none of the cases could he discover evidences of hereditary tendency to insanity. Out of the six, four died, one completely recovered, and one was still in progress. In all the cases except one the renal secretion was carefully watched, and in none did the kidneys appear to be factors in the mental state. In four not a particle of iodoform was used at any time, and in the other two this drug was used, according to his custom, very cautiously and entirely on the line of cutaneous union, where absorption is next to impossible. He also felt very confident that none of his cases were instances of sudden and severe septicæmia marked by delirium.

It would be seen, he continued, that when his cases were added to those reported by others twenty-six instances of acute mental aberration following upon the performance of gynecological operations, were now placed on record. In concluding, he said that the following questions had suggested themselves to his mind in connection with this subject:

1. Were these twenty-six cases of mania and melancholia really due to the operations which immediately antedated them, or did they follow as mere coincident states, *post hoc, sed non propter hoc?*

2. Any great mental strain may be followed by mania. Is it at all remarkable that in the vast number of gynecological operations which have been performed during the last quarter of a century, in America and Germany, twenty-six cases of this malady should have occurred?

3. If the mania which followed operative procedures in these twenty-six cases was a consequence of them, how in the future is a tendency to the accident to be avoided?

4. Are the operations of gynecology any more likely than other surgical procedures, to disturb the condition of the mind?

P. B. P.

An Honorarium Well Merited.

Dear Sir:—The enclosed slip is such a rare compliment paid to one of our profession that I think it deserves notice. It is as follows:

Be it ordained by the Municipal Assembly of the City of St. Louis, as follows:

SECTION 1. The sum of five hundred dollars is hereby appropriated from the fund to pay Dr. A. C. Bernays for medical attendance on Murty O'Sullivan, a member of the police force, from June to September, 1888, who was injured in discharge of police duty on June 26, 1888, and the Auditor is directed to draw his warrant on the Treasurer for the above amount and deliver the same to Dr. A. C. Bernays, taking his receipt in full.

SECTION 2. There is hereby appropriated and set apart out of municipal revenue to pay Dr. A. C. Bernays the sum of five hundred dollars.

Approved March 30, 1889.

The municipal assemblies of a large city pass an ordinance to pay a doctor \$500 for a successful surgical operation on a policeman who was shot in the abdomen while attempting to make an arrest. The stomach, abdomen and jejunum required to be sutured. The laparotomy was done a few hours after the accident. Truly the world is getting better, and our profession is being recognized by a city assembly.

Respectfully,

W. W. KINGSBURY, M.D.

St. Louis, April 17, 1889.

NECROLOGY.

Samuel W. Gross, M.D.

Samuel W. Gross, M.D., Philadelphia, Pa., Professor of Surgery in the Jefferson Medical College, died on Tuesday the 16th inst., at the age of 52 years. He was a son of the late Samuel D. Gross, so long at the head of the surgical profession in this country, and was born in Cincinnati, O., while his father was occupying the chair of Pathological Anatomy in the Medical College of Ohio. He was educated in Shelby College, Ky., and graduated in medicine at Jefferson Medical College, Philadelphia, in 1857. He entered directly upon the practice of his profession in the last-named city. He served as Brigade Surgeon and Major of Volunteers through the Civil War,

and was brevetted Lieutenant-Colonel at its close.

He has made several valuable contributions to medical literature, for the most part on surgical subjects. Perhaps his "Practical Treatise on Tumors of the Mammary Gland" contributed more to enhance his reputation as a writer than any other. Although he had filled the chair of Surgery only since his father's death in 1884, he had earned a good reputation as a didactic and clinical teacher. His death came unexpected, in the vigorous period of manhood.

BOOK REVIEWS.

HANDBOOK OF THE DIAGNOSIS AND TREATMENT OF SKIN DISEASES. By ARTHUR VAN HARTLINGEN, M.D., Professor of Diseases of the Skin in the Philadelphia Polyclinic and College for Graduates in Medicine; Clinical Lecturer on Dermatology in the Jefferson Medical College. Second Edition, Enlarged and Revised, with additional Plates and Illustrations. Philadelphia: P. Blakiston, Son and Co. 1889.

This is a neatly published octavo volume of 410 pages, designed by the author as a plain treatise on the diagnosis and treatment of the various diseases of the skin, such as would be most useful to the general practitioner. The issue of a second edition with important additions is sufficient evidence that the work has met the approval of the profession.

A CLINICAL ATLAS OF VENEREAL AND SKIN DISEASES; including Diagnosis, Prognosis and Treatment. By ROBERT W. TAYLOR, A.M., M.D. 192 Figures, 58 Colored Plates. Parts V and VI. Philadelphia: Lea Bros. and Co.

The earlier fasciculi of this work have been already noticed. These maintain the standard of excellence of the others. The plates are exceedingly good. The subjects illustrated in these numbers are Urticaria, Pemphigus, *Tinia Tricophytina* Barbæ, *Tinia Circinata*, Ecthyma, Lupus Erythematosus, Herpes Zoster, Pediculosis, Erythema, Erythema Circinatum, *Tinia Versicolor*, *Tinia Tonsurans*, Pityriasis Rubra, Dermatitis Exfoliativa, Impetigo Herpetiformis.

MISCELLANY.

AN INTERNATIONAL CONGRESS OF OTOLGY AND LARYNGOLOGY will be held in Paris from the 16th to the 21st of September, 1889. Professor Duplay is President of the Committee on Organization, and Dr. Lœwenberg, rue Auber, 15, à Paris, Secretary, to whom all communications should be addressed.

STATE MEDICAL SOCIETY OF ARKANSAS.—The Fourteenth Annual Session of this Society will be held at Pine Bluff, commencing on Tuesday morning, May 28,

1889, and continue three days. A full attendance and a profitable meeting is expected. For further information apply to L. P. Gibson, M.D., Secretary, Little Rock, Ark.

AMERICAN CLIMATOLOGICAL ASSOCIATION.—The next annual meeting of this Association will be held in Boston, June 24th and 25th, 1889, just prior to the meeting of the American Medical Association at Newport. Dr. V. Y. Bowditch, of Boston, President. An interesting series of papers have been secured and the meeting promises to be a very successful one.

ILLINOIS STATE MEDICAL SOCIETY.—The Local Secretary at Jacksonville, Dr. T. M. Cullimore, informs us that the list of railroad companies named below have agreed to carry delegates at reduced rates to the meeting of the Illinois State Medical Society to be held in Jacksonville, May 21st to 23d. The rate will be one and one-third fare, on the certificate plan. Delegates must consult local agents for instructions as to procuring certificates, and certificates must be countersigned by Local Secretary. Chicago & Alton; Chicago & Northwestern; Chicago, Burlington & Northern; Chicago, Burlington & Quincy; Chicago, Milwaukee & St. Paul; Chicago, Rock Island & Pacific; Chicago, St. Paul & Kansas; Chicago, Santa Fe & California; Illinois Central; Rock Island & Peoria; Wisconsin Central Lines; Wabash; and Jacksonville Southeastern.

IOWA STATE MEDICAL SOCIETY.—The Iowa State Medical Society will meet this year at Keokuk, on May 15th, and will continue in session three days. President, Donald Macrae, M.D.; Secretary, S. S. Lytle, M.D.

The American Association for the Advancement of Science meets at Toronto, Canada, August 27, and will remain in session until September 3, inclusive.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from April 13, 1889, to April 19, 1889.

Major John W. Williams, Surgeon U. S. Army, died at Jackson Bks., La., April 15, at 5 o'clock p.m.

Major John C. G. Happersett, Surgeon U. S. Army, is relieved from duty at Willet's Point, N. Y., and ordered to report to the commanding officer, Atlanta Bks., Ga., for duty as Post Surgeon at that post. Par. 12, S. O. 88, A. G. O., April 16, 1889.

First Lieut. Charles E. Woodruff, Asst. Surgeon U. S. Army, is relieved from duty at Ft. Mackinac, Mich., and ordered to Ft. Gaston, Cal., for duty. Par. 14, S. O. 86, A. G. O., April 13, 1889.

Lieut.-Col. James C. McKee, leave of absence granted in S. O. 44, A. G. O., February 21, 1889, is extended seven days. Par. 11, S. O. 86, A. G. O., April 13, 1889.

Capt. Adrian S. Polhemus, Asst. Surgeon U. S. Army, is relieved from duty at Ft. Gaston, Cal., and ordered to Ft. Monroe, Va., for duty. Par. 14, S. O. 86, A. G. O., April 13, 1889.

Major Clarence Ewen, Surgeon U. S. Army, promoted Surgeon U. S. Army, with rank of Major to take effect April 15, 1889.

Capt. Aaron H. Appel, Asst. Surgeon U. S. Army, is granted leave of absence for twenty-one days. Par. 1, S. O. 38, Hdqrs. Div. of the Missouri, April 16, 1889.

Hdqrs. Dept. of Dakota, St. Paul, Minn., April 8, 1889. Special Order No. 35: Under authority from the Secretary of War conveyed by letter of the 16th ult. from Division Headquarters, the post of Ft. Sisseton, Dak., will be discontinued June 1, 1889.

Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending April 20, 1889.

P. A. Surgeon James C. Byrnes, detached from special duty at Norfolk, Va., and to the "Chicago."

P. A. Surgeon A. C. Heffenger, granted leave of absence for six months, with permission to leave the United States.

P. A. Surgeon Philip Leach, leave of absence extended six months, with permission to remain abroad.

Asst. Surgeon C. H. T. Lowndes, ordered to Naval Academy, Annapolis, Md.

Asst. Surgeon A. M. D. McCormick, detached from the "Vermont" and ordered to the "Chicago."

THE REMEDY FOR OVERCROWDING IN
THE MEDICAL PROFESSION.

Read before the St. Clair County (Ills.) Medical Society, Dec. 6, 1888.

BY BOYD CORNICK, M.D.,
OF MASCOUTAH, ILL.

That the medical profession is overcrowded, is a fact of the gravest import, recognized by physicians everywhere. The lamented Dr. Garnett, in his address as President of the American Medical Association, devoted his entire paper to an earnest and able discussion of this evil, and to suggestions for its abatement. State associations, district and county societies, current medical periodicals and individual physicians, both here and abroad, are manifesting the liveliest concern in the solution of the problem, which is everywhere increasing in importance.

Before proceeding to discuss remedial measures for a recognized evil, let us first consider the essential nature of the disease which we wish to combat. What constitutes an overcrowding in the ranks of the medical profession? How large may be the ratio of physicians to total population without exceeding a reasonable and natural proportion?

We know that in the United States there are more doctors to the 10,000 of general population than in any other country in the world; and yet it may reasonably be doubted if the average income received by American physicians is less than that enjoyed by medical men abroad. On the contrary, it seems to be a well ascertained fact that the average, both of medical fees and of the incomes of medical practitioners in this country, exceeds that prevailing in any other country on the globe. And the cause of this is not far to seek. The average prosperity of the whole people of this country exceeds that of any other people in the world; and doctors, like all other citizens who labor for a livelihood, receive their proportionate share of the prosperity or poverty of the particular country in which they live. In Great Britain there are fewer doctors to the 10,000 of total population than with us, and on the continent of Europe a still smaller ratio, yet this fact does

not give the average medical practitioner abroad any advantage in point of professional income, over his American brother. For, though his patients be more numerous, yet the poverty of the masses of the people, among whom he practices his profession, compels him to accept lower fees and a smaller total income.

It is manifest, therefore, that where prosperity prevails among the people a larger proportionate number of physicians may enjoy comfortable incomes than where the people are steeped in poverty. Were *all* the citizens of the United States sufficiently prosperous to be able to pay reasonable fees for medical services, who could then say that we have too many doctors? But if our citizens, on the contrary, were as largely sunken in the depths of poverty as are the masses of the people on the continent of Europe, who could then deny that the American medical profession would be overcrowded, even though half its number were blotted out of existence within twenty-four hours? For the sake of argument imagine nine-tenths of the citizens of this country to be in the possession of incomes sufficiently ample to purchase the satisfaction of all the material desires incident to modern civilization, and he would be a bold man who should then declare the medical profession to be overcrowded, even were the existing ratio of physicians to general population in the United States doubled, trebled or, indeed, quadrupled.

The criterion, then, by which we may determine when the profession is overcrowded, is not alone the ratio of physicians to total population, but this ratio *taken in connection with the degree of poverty or of prosperity prevailing among the masses*. Bearing this conclusion in mind, we are now in position to consider the remedies which have been offered for the abatement of the universally recognized evil, which is now everywhere under discussion.

Many plans have been proposed for remedying the evil, and many have been tested; but none has yet been presented which on trial has proved to be efficacious. So far as I have observed, every plan which has hitherto been recommended has for its first aim such extension of the course of medical study preliminary to acquiring a diploma, and such elevation of the standard of ex-

aminations prerequisite to securing a license to practice, as would be calculated to deter many medical students of limited financial resources from entering on so difficult and expensive a pursuit; and induce them rather to choose some easier and cheaper, though possibly even more overcrowded avenue, than the practice of medicine, in which to seek honor, reputation and a livelihood.

But if stringent laws, regulating the course of study and the qualifications for practice, could solve the problem of an overcrowded profession, then Germany would have settled the matter long ago. Such laws do accomplish one desirable end which is good in itself; and that is, they elevate the standard of knowledge requisite to entering on the grave responsibilities of medical practice. And, in so far as they do this, they are highly to be commended. But restrictive laws and regulations, in so far as they are designed to prevent the evil of overcrowding in the ranks of the profession, "have" so far, to quote the language used by President Garnett, with reference to the less stringent regulations hitherto in operation in the United States, "proved conspicuously futile." And, in the humble opinion of your essayist, restrictive laws of all kinds must, in the nature of things, continue to prove conspicuously futile to the end of time.

Why is it that there is an "almost universal desire prevailing among the working classes to become doctors and lawyers?" Why is it that "the professions of law and medicine are overcrowded?" That the statements, as made by the late President Garnett, are hardly overdrawn, will be admitted on every hand. There must be a cause for this condition of things, as there is for every other ill from which humanity suffers. And it is a rational step for medical men to seek first the cause of an evil which so vitally affects themselves, before resorting further to empirical remedies which have always hitherto proved so "conspicuously futile" in affording relief. For if an efficient cause can be found for this condition which confronts us, and if this cause can be removed, then the disease will disappear, and our problem will have received a solution at last.

That "men seek to gratify their desires with the least exertion" is a fundamental law of human nature dominating every human being. And this law has no exceptions; for should at any time an apparent exception be noted, it will on investigation, like the apparent exceptions to the physical law of gravity, but prove how invariable is the rule. If, then, the assertion that "an almost universal inclination prevails among the working classes to become doctors and lawyers" be true, or indeed but half true, it is for the simplest reason in the world, viz: Because energetic and quick-witted young men in the ranks of the working classes can, by becoming doctors and

lawyers, gratify their desires with less exertion than they would be compelled to put forth in such other pursuits and avocations as are open to them. And just as long as society is constituted as it now is, so that a given *quantum* of exertion devoted to the study and practice of medicine yields, or promises to yield, larger returns than in some other avocations, *so long will the present tendency continue* for men to gravitate from other avenues of gaining repute, respectability and a livelihood into "the business of doctoring"—I trust I may be pardoned the expression.

Germany is probably excelled by no other government in the world in the stringency of its laws regulating admission to the ranks of the medical profession. Not only is the preliminary course of study long and arduous, not only must each aspirant have passed through every successive grade of prescribed preparatory instruction, not only must he have secured the endorsement of some noble university, justly famed for the high standard of learning which its degrees imply; not alone must the aspiring youth devote many years of time and many hundreds of *thalers* to a completion of the course marked out for him by the authority of the State; but in addition to all this, even though the possessor of a university degree, he must finally pass a rigid and awe-inspiring *Staats-examen* before a government licensing board; and then, if successful in this latest ordeal, he is permitted to practice medicine within the confines of the German Empire.

As a consequence of all these stringent requirements, the medical profession of Germany leads the vanguard in the world-wide march of progress in the medical sciences. Such results certainly justify the high standard of qualification requisite for entrance into the medical profession of Germany. But, alas! even in that favored land, whose laws regulating the practice of medicine are exceeded in stringency by those of probably no other government under the sun, we are confronted with the same problem of an overcrowded medical profession, which is harrassing the minds of medical men throughout the confines of our civilization. For, as with us so also in Germany, the same widespread inclination prevails among the working classes to become doctors and lawyers. And, in spite of the highest degree of restrictive legislation which may be deemed possible or even desirable, the ranks of the learned professions are in Germany even more overcrowded than with us, if we may take as a criterion the relative fees and the average professional incomes prevailing in the two countries respectively.

The explanation of this is simple and the cause is not difficult to find. As in the United States, so also in Germany, men seek to gratify their desires with the least exertion. It requires far more exertion in Germany to obtain a license to prac-

tice medicine than is requisite in the United States, *but it is also far more difficult there than with us to earn a living in every other avocation.* And the proposition holds good for Germany, as it does also throughout the civilized world, that, as it becomes increasingly difficult for the average man of average intelligence to earn a satisfactory livelihood in all other avocations, he will lightly turn to the thought of "doctoring," with a view to bettering his condition. And it must in the future continue to be as invariably true as it now is, that so long as "the working classes" find it relatively more irksome and laborious to secure the gratification of their desires in other avocations than in the practice of medicine, so long will they persist in overcrowding the medical profession. Laws requiring of students the expenditure of more time and the outlay of greater effort than are now necessary to the acquirement of a license to practice medicine, should undoubtedly be enacted in our country also; because more stringent laws in this direction are manifestly needed in order to elevate the existing standards of qualification for medical practice. But, if I correctly apprehend the drift of the argument put forth in the address of President Garnett, *such laws, if only stringent enough, are also expected to solve the problem under discussion,* and to check the recognized tendency of the working classes to become doctors, by requiring of them *so great exertion* in the attainment of their object as to make them rather content with some other pursuit, less remunerative may be, but also far less burdensome to follow.

Restrictive legislation will not solve this problem. Its solution lies not in restriction but in freedom—freedom on the part of the working classes (including doctors) to produce wealth and secure the satisfactions of their desires by equal privilege of access to the bounties of nature. Let us beware of advocating restrictive legislation of such character as may be calculated to invite public hostility to the medical profession. Let us avoid the suspicion of seeking to build up a close trades-union, a medical guild, a professional trust, a close corporation—seeking our own advantage (it is suspected) at the expense of the public at large. Laws operating in this direction do not, and cannot, afford a solution of the problem, but rather retard its solution. The remedy which we are seeking does not consist in making it *more difficult* for "the working classes" to become doctors, *but in making it less difficult to earn an honest living in all other avocations.*

Whenever our existing taxing laws, which now levy a fine on every product of labor, and which by fining, also restrict every form of wealth production—thereby promoting the poverty of "the working classes" (including doctors)—shall be so amended as to take by taxation for public purposes those values, and those values only, which

pertain to land, irrespective of improvements; and which, being produced by the whole community, should rightfully belong to the people at large; then will every form of wealth production be unfettered, and every citizen be at liberty to earn a living by applying his labor, on equal terms with every other citizen, to nature's inexhaustible store-house of raw materials. And since the power of labor, in transmuting raw materials into wealth, has, in our own generation, been multiplied a thousand-fold by the aid of steam engines and labor-saving machinery; and because nature is lavish of her bounty, and all forms of raw material are practically inexhaustible; it follows that, if all men secure equal privilege of access to nature's inexhaustible stores, the production of wealth in all its forms will be practically limited only by the complete satisfaction of every material desire of the human heart, and the wildest dreams of avarice be more than realized, to the practical benefit of the entire human family without exception. Under such a system of taxing laws involuntary poverty will of necessity be abolished, and every man will be free and untrammelled in earning a livelihood in whatever avocation promises to secure the satisfaction of his desires with the least possible exertion.

And when this practical and far-reaching reform shall have been accomplished, by virtue of a simple change in our existing taxing laws, as I have faith to believe it shortly will be, men will not be tempted to overcrowd the medical profession, at the cost of years of irksome preparatory labor, unless they are constrained to do so by higher and nobler motives than *simply* to gratify their desires with the least exertion. And the enhanced general standard of comfort, and increased ease of earning a livelihood then prevailing among the people at large, when the existing barriers to profitable employment in other avocations shall have all been swept away, will react favorably upon the medical profession also; not only by removing the present incentives to study medicine on the part of those who are better fitted by nature for other pursuits, but by enabling many hundreds of thousands of honest men to pay adequate fees to their family physicians for services rendered, instead of, as now, seeking medical charity for very poverty's sake at some free dispensary.

Then will our problem be finally solved. But a new one of opposite tenor will spring up, a solution of which which will be called for, not by the medical profession, but by the public at large. The problem will then read, not "How shall we prevent unlearned men from gravitating toward the learned professions?" but rather "How shall the pecuniary reward be made sufficiently great, to induce men of talent to devote the years of time and labor needed to qualify them to enter upon the laborious and responsible professions of law and medicine?"

THE TREATMENT OF PELVIC INFLAMMATIONS.

Read before the Section for Clinical Medicine, Pathology, and Hygiene of the Massachusetts Medical Society, Dec. 12, 1888.

BY M. ROSENWASSER, M.D.,
OF CLEVELAND, OHIO.

In the management of cases of chronic pelvic inflammation the accurate diagnosis is a highly essential element, without which the practitioner is entirely at a loss to know what to do and what to leave undone. The differentiation between the various conditions apparently identical to the touch requires a careful review of the history and symptoms, and experienced tactile sense and frequently repeated examinations at various intervals. If a careful examination were made under anæsthesia, in the exaggerated lithotomy position, whenever the diagnosis was not sufficiently clear, many false conclusions could be eliminated. There would then be fewer cases of pelvic exndations treated as uterine displacements by the use of the sound and pessary: the number of uterine fibroids, so gracefully and rapidly dispersed by electrolysis would in a degree diminish, and pelvic cellulitis would be relegated to its proper place in pathology as a phlegmonous inflammation.

If there is any disease in which a difference in treatment based on the social condition of the patient is allowable, it is in these pelvic troubles. The washwoman, the cook, the shop-girl, the seamstress, in short, women dependent for support on their own earnings, will consent to any operative proceeding which promises them speedy relief and the early resumption of the work which alone protects them against a pauper's lot. In these instances the early operation is a boon, and the long-drawn-out treatment under adverse circumstances, an unwarranted makeshift. On the other hand, patients whose resources enable them to carry out strictly the demands of a palliative treatment ought to be made acquainted with this alternative before counselling radical measures, except where such measures are vitally indicated. While many of this class of patients are rendered comfortable from time to time by palliative treatment, and an exceptionally few may be permanently cured, it is to be regretted that some authors, through reports of incomplete cases, mislead the practitioner into the belief that the majority of such cases are curable without resort to surgical interference; that the hot douche, the supporting tampon, the application of iodine, and especially the use of galvanism, are the means by which the congestions are relieved, the adhesions softened and finally absorbed, the displacement rendered accessible to correction, in fact, the patient completely restored to health.

My own experience does not fully agree with this roseate view. The following cases, whose histories will be alluded to in outline only, are

without doubt representative of numerous similar cases under the care of other physicians. They have one characteristic in common, and that is, their long duration, which renders them so much the more typical of the class now under discussion.

Case 1.—Age 30. Married seven years. Mother of one child 6 years old. Consulted me a few months after confinement. Complained of nervous disturbances, severe backache and great weakness, partly due to semi-monthly recurrent menorrhagia. Examination revealed a subinvolved, retroverted uterus with chronic endometritis. The application of iodized phenol and the retention of the uterus in its proper position by a hard rubber pessary relieved the patient. In an unguarded moment, a brood of bacteria found access into the pelvis, causing a subacute pelvic peritonitis. When the patient recovered after an illness lasting four months, we (Dr. G. C. E. Weber being my consultant) found retroverted uterus bound by adhesion, and the ovaries large and exceedingly tender. After the uterus had been freed and replaced, the shortened uterosacral ligaments could be felt as sharp, rigid bands, raising the vaginal vault in corresponding folds. The continuous traction and its reflex results not yielding as rapidly as the patient had hoped, she consulted Dr. T. G. Thomas, of New York, and remained at his private hospital for six weeks, where she underwent some local but mainly general constitutional treatment. She returned improved, but still ailing; she finally became pregnant, and was confined last July. She is now in better health, but is still wearing a pessary, without which she is miserable, and is not yet cured. This being a case of chronic ovaritis with pelvic adhesions, of right belongs to what might be called the border-line between limited and general pelvic peritonitis, and represents the most satisfactory result obtainable by patient, non-surgical therapeutics.

Case 2.—Age 33. Married. Mother of three children, last being 4 years old. Was in good health until three years ago. Gonorrhœal infection progressively traceable from urethra and vagina to uterus and tubes, having caused a moderate pelvic peritonitis. Six weeks after recovery from acute symptoms, examination reveals, besides enlarged and tender ovaries, the presence of a round, smooth, fluctuating movable tumor of the size of a small orange, not specially tender, occupying the right side of the pelvis; examining a few days later only the thickened relaxed walls of the sac formerly filled with fluid could be felt, with increased sensitiveness of the posterior surface and fundus of the uterus. There was at no time after subsidence of the peritonitis any vaginal or uterine discharge, except her normal and moderate menstrual flow; nor was there any elevation of temperature. After the lapse of a few weeks, the tumor would refill and disappear

as before, leaving some sensitiveness posterior to the uterus as high as the fundus. Occasionally a similar tumor would form and vanish on the left side. These recurrences were not connected with the menstrual function. Dr. Weber, consultant in this case also, on one occasion accidentally burst the sac by too strong pressure, but no harm followed. There is no room for doubt that we have here an unique condition of irregular, alternating hydrosalpinx, which discharges its contents into the retro-uterine pouch. The fluid, not acrid enough to inflame, but only to irritate, gradually distends the occluded or highly constricted tube, and by the continually increasing pressure forces its way out either through a narrow angular canal or by rupture at some weak spot, which then is repaired, to be again broken when the sac is filled. The patient is still under observation and occasionally takes to her bed when she feels a new rupture has occurred. She has not been pregnant since her sickness, nor is she likely to be. Whether she will ultimately get well, or at some period require surgical assistance in case of suddenly developing peritonitis, time will tell.

Case 3.—Age 30. Married seven years. Sterile. Menstruation generally profuse. Copious leucorrhœa. Suspected infection. Three years ago, while under another physician's care, she took a severe chill; pelvic peritonitis developed, with formation of abscess in the left side of the pelvis in the course of a few weeks. The abscess burst into the bladder; before the abscess wall had collapsed Dr. Dudley P. Allen, consultant, made a counter opening from the vagina, and thus drained the abscess, which finally healed after a tedious and very painful illness. The patient has been about for a year, but is still a sufferer. There is quite a bunch of induration to the right of the uterus, besides the retracted cicatrix on the left.

Case 4.—Age 45. Married twenty-three years. Sterile. Menstruation irregular, at long intervals. For the past five years afflicted with vague pains in the pelvis and back, with considerable leucorrhœa. The uterus is enlarged, the vaginal vault tender on pressure, but no distinct tumor can be felt. Being otherwise a sufferer from chronic congestion of the liver, she has not laid much stress by her pelvic symptoms. Two years ago she was suddenly seized with violent pains, beginning in the pelvis and spreading rapidly over the entire abdomen. After recovering from the severe general peritonitis of three weeks duration, a large, hard, sensitive mass filled the retro-uterine space. Several weeks later, the patient found she was passing large quantities of offensive purulent material with each defecation. From this time forward she continued improving, but was still far from well. She made a trip to Germany with a letter to Prof. Aug. Martin, of

Berlin, submitting the case to him for operation. In his reply he confirmed the presence of pyosalpinx with communication into the bowel, but had decided first to try the effect of curetting the uterus before undertaking abdominal section. The patient had improved so decidedly upon that treatment that he discharged her as cured. On her return I found her much improved, but the mass posterior to the uterus had not disappeared. During the past summer she was on several occasions compelled to remain in bed for days, once for a fortnight, when the pelvic mass had become tender, and had rendered her unfit to be about. There has been no discharge of pus from the bowel during the past few months.

The last two cases have had a mixed treatment. The former required surgical interference to save her life, for I am convinced she would have died without drainage. I cannot understand the principle underlying Martin's treatment of the latter case. It was only palliative; for he could not expect the diseased tube to become absorbed or permanently drained, nor would the expected menopause have any influence on a pyosalpinx.

I now quote from E. H. Grandin's citation of Mundé, who completes his history of a case of pelvic peritonitis in this wise: "As soon as she was able to come to my office, I recommended the galvanism, and after about a month's treatment she was as well as ever, and was discharged last March, wearing a small, soft-rubber, Albert Smith pessary, which she thought gave her some support in walking. I gave her directions about the continuance of the galvanism, and have not heard from her since. Hence I infer that she is doing well, as she was of the kind of patients who would be sure to let me know if my treatment had not proved effectual." This to justify my assertion that incomplete cases are wrongfully reported as cured.

The results already attained by men prominent in the surgery of the pelvis warrant the belief that early operations in pyosalpinx will become the established rule; that hæmato- and hydrosalpinx must be treated according to the individual indications, expectantly or by removal, if peritonitis repeatedly threatens life or seriously impairs health. When we shall have become as familiar with the after-histories of abdominal sections for ovaritis and pelvic adhesions as we are with the natural history of this variety of pelvic peritonitis, it may become possible to differentiate cases fit for operation from those unsuitable. Such cases are too often discharged from hospitals, and completely lost sight of, when it is of the utmost importance to know what benefit finally was resultant from an operation not yet fully conceded to be justifiable.

ERYSIPELAS AND PUERPERAL FEVER.

Read before the Gynecological and Obstetrical Society of Baltimore,
February 12, 1889.

BY ROBERT T. WILSON, M.D.,
OF BALTIMORE.

GYNECOLOGIST TO THE UNION PROTESTANT INFIRMARY; ASSISTANT
SURGEON TO THE HOSPITAL FOR THE WOMEN OF MARYLAND.

The more the study of infectious diseases rules the medicine of the present time, the more our interest is directed toward the relation which the individual diseases bear to each other. Among the infectious diseases which, according to the old ideas, are said to stand in a changeable relation to each other, are erysipelas and puerperal fever. The endeavor has been made to prove clinically the identity of both diseases by pointing to the fact that they appear simultaneously, and still further by showing that puerperal fever is said to be engendered by erysipelas, and *vice versa*, in the case of lying-in women. The views of the identity of both forms of disease are especially furthered by the opinions of Virchow that, anatomically considered, the course of certain forms of puerperal infectious diseases, especially in the cellular tissue of the pelvis, resemble, or indeed are the same, as in erysipelas. There are statements enough in existence which must make us cautious in our practice, but which are always being opposed by a number of observers, and these, though widely differing, assist in proving that there is a connection between erysipelas and septic infection. This subject, which has been treated in a great variety of ways, has made great progress in recent years through the fact that Volkmann (Pitha—Billroth's Chirurgie, Erysipelas), lays stress upon the point that erysipelas as a disease, *sui generis*, must be separated just here in the puerperium from the phlegmonous conditions—a view which has already been expressed by others (Hirsch). Hugenberger, from his experience, has endeavored to show that erysipelas in the puerperium only appeared as a dangerous complication and had nothing to do with puerperal fever. We find cases on record in which erysipelas appeared to an alarming extent in lying-in women as well as in other patients—so-called *noso-comial* erysipelas; and further, that septicæmic conditions and pyæmia have been engendered from lying-in women with erysipelas, and *vice versa*; from such lying-in women erysipelas has occurred with other sick persons or with well persons—physicians, nurses, etc.

After the appearance of Hugenberger's communications, A. Gusserow, in the spring of 1879, had under his care a large number of erysipelas cases with lying-in women, while at the same time many cases of puerperal fever appeared in the obstetrical ward of the Charité Hospital. From the course of the cases of *noso-comial* erysipelas (says Gusserow), if we are willing thus to designate the coincidence of nine cases of gen-

uine erysipelas, he (Gusserow) was thoroughly convinced that there existed no connection between puerperal sepsis and erysipelas. The discovery of Fehleisen has made an epoch in the study of erysipelas, and it involuntarily recalls to our recollection (says Gusserow), the question how far erysipelas stands in connection with septic infection in the puerperium. Since through the erysipelas coccus (says Gusserow), the specific principle of erysipelas, the peculiarity of the disease has been so beautifully proven, it seems to me (says Gusserow) that now is the time to emphasize again, from a clinical standpoint, the individuality of erysipelas in the puerperium, and to endeavor to prove that this disease has nothing in common with puerperal sepsis (*Archiv. f. Gynäk.*, vol. xxiv, part 2). Medical literature contains a sufficient number of cases with observations on the course of erysipelas in pregnant women to substantiate this view.

If erysipelas could be easily produced from a lying-in woman who has puerperal fever, the number of observations ought to be very large. But in the literature of this subject the cases on record are by no means large, and those which do exist admit of the supposition that they are not genuine erysipelas, but phlegmonous inflammation whose connection with sepsis is known *in those cases* (says Gusserow). Puerperal fever, puerperal septicæmia, may be endemic or epidemic. As the symptoms of the affection vary infinitely, so may the epidemics in their severity. Since the first epidemic at the Hotel-Dieu, recorded by Mauriceau and Lamotte, 1664, hardly a year has passed without our being able to refer to an epidemic at one or another place in the different parts of the world. While all authorities agree in regard to the application of the term puerperal fever, the theories of its origin have been innumerable, and to-day there are questions concerning it which it remains for the future to decide. The earliest theory was based on the idea of retention of the lochia, with decomposition of remnants of placenta. This theory started with Hippocrates, and was defended by Galen, Avicenne (1000), Rhodion (1532), Mercatus (1570), Michaelis (1615), Sennert (1631), Sydenham (1682), Hüter (1711), Mauriceau (1712), Burton (1751), Smellie (1752), Tissot (1795), and many others. To this theory succeeded that of the metastasis of the milk, which was first promulgated by Mercurialis and Willis, in 1662, and was advocated, in particular, by Puzos (1743), Licutand (1750), Levret (1766), Van Swieten, Deleurye (1777), and others. Autenreith formulated his theory in the beginning of this century, which is only a combination of the preceding. His theory was accepted by Schmidt-müller, Carus, Joerg, etc. Then arose the gastro-bilious theory of Trincavellus, which was advocated by Manning, Cooper, Denman, and others. The fifth theory is the phlogistic; according to

which inflammation is the cause of puerperal fever. According to the site of the inflammatory process, we may have three varieties: 1. A metritis, which may be associated with a phlebitis or a lymphangitis (Plater, 1602, Denman, Tissot, Naegelé, and others). 2. An enteritis and a peritonitis. 3. Peritonitis, pure, the view of Johnston, Hunter, Siebold, Capuron, Bandelocque, and others. Then followed the erysipelatous theory, advocated in particular by Eisenmann, and accepted by Delaroche, Bayrhafer, Gordon, Ingleby, Lee, and numerous English and American authorities; this theory considers puerperal fever an internal erysipelas.

Semmelweis, in 1847 to 1861, promulgated the following theory: Puerperal fever must always be considered as a fever due to the absorption of a decomposed animal organic matter, and, this absorption may result from *auto-infection* (the product of decomposition coming from the individual itself), or from *hetero-infection* (the product of decomposition coming from without). Puerperal fever is not, therefore, a peculiar and exclusive disease of the puerpera. An identical affection, even as has been proved by Trousseau, Schée, Helm, Buhl, Simpson, Tarnier, may be met with in virgins, in the new-born, in wounded of either sex. The point of origin of the disease is found as well in the uterine wound, and in slight superficial wounds of the genital organs, as in lesions of the peri-uterine cellular tissue, or in the vagina. The primitive local disease becomes general through the carrying of the morbid process to the cellular tissue, thus gaining in extent, or else it is transported by the lymph of the blood to all the other organs; or else foreign bodies are carried by the circulation, deposited in different organs, and there become the source of the disease.

The causes of isolated cases, that is to say, of those developing aside from all epidemic influences are:

1. Lesions and wounds of the genital organs.
2. Retention followed by alteration of portions of the placenta or of the membranes.
3. Primitive inflammation of the vagina and of the uterus, such as those caused by gonorrhœa.
4. Finally, infection of wounds of the genital organs by cadaveric emanations, purulent or gangrenous secretions, etc.

Schroeder is a resolute advocate of the theory of Semmelweis. Doléris says: To-day all authorities are in accord in considering puerperal fever as a species of poisoning. The most resolute localists have renounced the view that the disease resides in the lesion itself. The recent investigations of Championnière, Siredey, Quinquand, Fioupe, Despine, Bode, plead in favor of the absolute similarity of puerperal and of surgical infection. This is the doctrine held in France, and the one stated by Winckel (1878). It is the doctrine admitted *almost* uniformly

throughout the world. In the United States, the belief of *almost* all accoucheurs is certainly in accord with the statements of Charpentier—puerperal fever is septicæmia, differing only from surgical septicæmia in that, superadded to infection, is the puerperal state. The most distinguished exception to this is Prof. Fordyce Barker; he still adheres to the views promulgated by him years ago, and it certainly tends to make every thoughtful man hesitate a trifle in propounding the absolute statement that puerperal fever is *always* simply puerperal septicæmia. In the memorable discussion before the New York Academy of Medicine, in 1884, when Thomas, with all his eloquence, plead for the entire identity of this fever with septicæmia, Barker protested alone against such a broad view, and stated that "his creed to-day is fully avowed in his book on the Puerperal Diseases, and unless in the future he learned new facts and new arguments to change his faith, he should die impenitent." In reference to Thomas' argument, he stated that its pathological doctrines were misleading and dangerous, because they were "super-saturated with septic infection." He (Barker) says that there does exist an epidemic disease differing in all characteristic points from what is known as septicæmia; differing in its origin, its modes of attack, its symptoms, its anatomical lesions. His conviction, therefore, is still that there is such a disease as puerperal fever *sui generis*. Lusk says, surgical fever and puerperal fever are not only analagous, but are essentially one and the same process. Of all who discussed Thomas' paper, only Mundé was inclined to agree in a measure with Barker. Mundé's views are best expressed in his recently published appendix to Cazeaux and Tarnier's Treatise on Obstetrics.

Gallabin holds that a puerperal fever, *sui generis*, may exist. According to Playfair there exists identity between puerperal septicæmia and surgical septicæmia, and there may be either *auto-infection* or *hetero-infection*.

Robert Barnes says, "that there are many points of analogy is undoubted; but there are also points of difference which forbid us to accept the doctrine of identity."

Atthill, Priestly, MacClintock, Macan, Johnston, admit that puerperal fever is only septicæmia, the result of ichoræmia.

Parvin, in his recent work on obstetrics says: "From what is known of so-called puerperal fever, it should not be regarded as a specific disease, and strictly speaking, there is no puerperal fever, that which is so denominated being a febrile affection caused by the entrance into the system of a poison from without, the nature of which we do not know, the entrance taking place through a wound of the uterus or of some part of the vulvo-vaginal canal."

Fortunately for the women, our treatment of

the disease is to-day more certain than our theory as to its origin, and if in the future a better explanation of the cause is offered than at present acceptable to the majority of accoucheurs, we do not hope for much change in the generally accepted treatment.

A CASE OF ACUTE YELLOW ATROPHY OF THE LIVER.

BY J. F. JENKINS, M.D.,
OF TECUMSEH, MICH.

James Muir, æt. 42 years, a shoemaker by occupation, had been complaining of pain in the region of the liver and stomach for upwards of two weeks previous to calling a physician. Dr. Geo. Howell, who attended him during the last week of his illness, and with whom I was called in consultation, gave the following history of the case: Upon examination, the patient's pulse ranged between 50 and 60 until within a few hours of his death, when it exceeded 100 per minute. The skin was jaundiced. The temperature never exceeded 100° F., and within a few hours of his death it was natural. There was slight nausea, but during the last week of his illness the patient neither complained of pain in the region of liver or stomach. The area of dulness over the liver rapidly decreased, so that its lower border could not be detected upon the most careful examination when the writer was called in consultation, which took place about seven hours previous to the death of the patient. At no time did he complain of headache, or pain in any portion of the head. There was a tendency to stupor during the last week of his sickness, but up to twenty-four hours of his death (which took place March 10, 1889,) he could be easily aroused and would answer questions rationally. During the course of the night previous to his death the patient vomited up a pint or more of dark grumous blood, looking very much like that which is described as the black vomit of yellow fever. The stupor then became more profound, the pupils of the eyes were largely dilated, there being marked oscillation of the eyeballs from within outwards and taking place within a certain degree of regularity, averaging about ten times per minute and continuing within a short period of his death.

A post-mortem examination was made by Dr. Howell in the presence of several physicians, about twenty hours after death. An incision was made, exposing to view the stomach, bowels and liver, showing that the latter organ was from one-third to one-half its normal size. Its upper surface was pale in color, studded here and there with patches having the appearance of rhubarb in color. The fluid in the organ was darker and thicker than natural. No microscopical exami-

nation was made. The stomach and spleen apparently were in a healthy condition. The kidneys were slightly enlarged. A short distance from the entrance of the gall duct into the duodenum was found an old ulcer partially healed, and which appeared to have no significance relative to the disease of the liver.

Remarks.—All modern writers agree that acute yellow atrophy is a rare disease. Strümpell states in his late work, that about 200 cases are recorded. Its etiology is somewhat doubtful. In the above case, the man was of temperate habits, and was not given to excesses of any kind.

REPORT OF A CASE OF GONORRHOEA WITH PURPURA RHEUMATICA.

BY W. A. PHILLIPS, PH.B., M.D.,
OF EVANSTON, ILL.

The occurrence of purpura as a complication of gonorrhœal rheumatism has been noted so seldom that I report the following case:

March 2. Mr. B., æt. 19, milkman, with a previous history of chronic gonorrhœa, has had an acute exacerbation since February 8; also an efflorescence on lower extremities since February 26; also pain and swelling of several joints, March 2.

On examination: penis œdematous; purulent discharge from urethra, containing gonococci; inguinal lymph glands swollen spindle-shaped. A symmetrically distributed efflorescence of anterior and inner aspect of leg, and inner aspect of thighs extending into gluteal regions; over left ankle, the most troublesome joint, skin thickly covered; also upper extremities present a limited number about the wrists; rest of body free. The great majority of the lesions macular, some slightly elevated, of definite, irregularly circular outlines; sizes varying from pin-head to one-cent piece in area; in color a deep bluish-red, not changing on pressure, a few of the larger and elevated ones changing at their edges on pressure, the uniformly deep color of their greater extent remaining. One large macule annular, others with small papules marking their centres. Between the larger and elevated spots great numbers of the smaller macules, some brighter red, others of the more prevalent bluish-red. No evidence of itching. *Joints:* Ankles swollen, left more than right; similar symptoms on the part of wrists, also metacarpal joints of both hands; parts in neighborhood of affected joints œdematous. No fluctuation. Temperature normal.

March 5. Ankles free, knees swollen and painful, left more than right. Prepuce œdematous, anteriorly a large macule, posteriorly a nodular body size of pea. Temp. normal. Photographed.

March 12. Sudden appearance of great numbers of wheals on lower extremities, varying in

size from that of a pea to the area of a silver half dollar; some bright red, not changing on pressure, others rose red fading on pressure, others colorless. No itching. Temp. normal. Older efflorescence brown, yellow.

March 13. Wheals had all vanished, leaving many fresh macules, largest of the size of a silver quarter. No change of symptoms had accompanied fresh outbreak. Exciting cause not determined. Joints nearly free. Patient states that he bled freely from a slight wound of right hand.

March 20. Joints free; color of efflorescence varying from brown to yellow. Urethral discharge, mainly mucus, slight. Urine contains many tripperfaden.

Remarks.—Thoracic and abdominal organs negative, also the mucous membranes, except urethral. There was no previous history of rheumatism. The majority of the skin lesions were purely of a hæmorrhagic nature. Some individual lesions were of the character of erythema nodosum. The fresh crop of March 12, purpura urticans.

REPORTS FROM HOSPITALS.

SURGICAL CLINICS AT THE WESTERN PENNSYLVANIA HOSPITAL BEFORE THE STUDENTS OF THE WESTERN PENNSYLVANIA MEDICAL COLLEGE.

BY PROFESSOR J. B. MURDOCH,

SURGEON TO THE WESTERN PENNSYLVANIA HOSPITAL AND PROFESSOR OF CLINICAL SURGERY IN THE WESTERN PENNSYLVANIA MEDICAL COLLEGE.

[Reported by WILL. N. PRINGLE, M.D., a member of the Graduating Class.]

October 6, 1888.

EXCISION OF THE KNEE-JOINT.

We show you to-day the patient on whom we did the excision of the knee-joint one week ago to-day. The dressings have not been disturbed since, and we bring him in here to re-dress his wound, that you may learn the *modus operandi* of changing the dressings of wounds. Now, in doing this, all the antiseptic precautions will be observed that were observed in the original operation. A wound like this is different from one made by the surgeon's knife. You remember this joint was a foul suppurating cavity, filled with pus. The poisonous germs were already there in great profusion. A wound made in sound tissue, by a surgeon's knife, if he be careful, may never become septic; the poisonous germs may never secure a lodgment in it, and it is in wounds like this before us that we frequently fail, because we are not careful enough in our management of them. Now that the dressing is removed from this wound, you see no evidence of suppuration in it;

these drainage tubes which have been in for a week are perfectly clean, so that we are not likely to fail in this case at least. These dressings might have been allowed to remain on for three weeks had it not been necessary to remove the drainage tubes. After a drainage tube has remained in a wound three or four days it has accomplished its purpose, and becomes foreign matter, and should be removed. In dressing a wound do not lay the first cloths or gauze on in straight flat layers, but rather loose, fluffy, or bunched; it absorbs much better than when laid flat. We next apply absorbent cotton and dress as before, taking care to apply enough absorbents to take up all the blood and serum that may exude. Whenever the discharge begins to show itself through the dressings, they should be removed at once, and the defect remedied. This man will now be returned to bed and his dressings will not be disturbed again for two weeks; unless pain or rise in temperature indicate that mischief is going on in the wound. You can see by his temperature chart that on the day of the operation his temperature rose to $101\frac{3}{4}^{\circ}$, and the next morning it had fallen to 99° , and in the evening arose to 101° . Since that time it has remained below 100° . You will see more of this man later on in the course.

ENLARGEMENT OF THE SCROTUM.

We have here another case which we will show you, a case of enlargement of the scrotum. Now there are various causes for enlargement of the scrotum, or many things that may be the cause of this state of affairs, and chief among them is hernia, which it is important to diagnose at once, when it is present; and in order to show you how to do it we will make a list of the conditions that might cause this enlargement. The following are some such conditions: Varicocele, hydrocele, enlarged testicle, hernia, orchitis, epididymitis, cystic disease, cancer, tubercle.

Now, varicocele is diagnosed by a peculiar knotty feeling of the contents of the scrotum, likened by somebody to the feel of a handful of fishworms. As I do not find any such feeling here, I erase varicocele. Hydrocele is diagnosed by its symmetrical, ovoid shape, and a translucency when held before a strong light; as these points are absent, we erase hydrocele. And as I can easily detect both testicles, and as they are of normal size and consistency, we exclude enlarged testicle, with all its causes. Now that all the other causes have been eliminated, we have diagnosed hernia, and as I can trace the mass up the inguinal canal to the internal ring, our diagnosis is verified. This is called differential diagnosis. This man was sent here for operation, and we had hoped to be able to do the operation for the radical cure of hernia, in your presence to-day; but since he has been in the hospital he refuses

to have an operation performed, and in this country when a patient refuses to have an operation performed we dare not do it, even if the country has to support the patient.

In the operation for the radical cure of hernia an incision is made from the internal abdominal ring down, well on to the scrotum; the protruded parts are returned to the abdominal cavity; a purse-string, catgut ligature is passed around the neck of the sac, which is then cut off and removed; the stump is placed within the abdomen and the internal ring closed with sutures. This is the operation in outline, and it is usually successful.

DOUBLE FRACTURE OF THE FEMUR.

Here is another poor man from Coal Bluff. While at his work in the mines last night a large amount of coal fell on him, injuring him, but how severely we know not, as we have not examined him yet, but will proceed to do so at once. You observe as he lays on his back that both limbs are everted, and some deformity above the left knee. Measurement in this case can afford us no information, because, both limbs being injured, we have no data from which to calculate. I will therefore raise the right limb, and by manipulating it I find a false point of motion about the middle of the right femur, which is plainly visible to you all, and although I fail completely to obtain crepitus, I still have sufficient evidence on which to base a diagnosis of fracture of the femur. Now, in manipulating the left leg, I am able to find a false point of motion, and to elicit crepitus, just above the condyles of the knee. We therefore have a double fracture of the femurs in this case; the fact that we get crepitus in the one case and not in the other, can be explained by the fact that in some fractures the bones glide past, or overlap each other, which is the case here. This overlapping is caused by the contraction of the muscles, which is sometimes overcome with great difficulty, and sometimes is never overcome. In regard to the treatment of fractures of the femur, you all know that formerly there was a great variety, but the almost universal method now of treatment is by extension and counter-extension; this, in old times, was accomplished by a long splint, and a perineal band. The perineal band was a great annoyance to the patient, for in passing around the perinæum it almost always irritated the parts, causing numerous ulcerations and sores.

In these days, and in this institution, extension is made by the weight and pulley, which represents the extension, and by raising the foot of the bed we get the counter-extension. This raising of the foot of the bed to get counter-extension has done away with the perineal band; it has also done away with a world of suffering for the patient. This is an American invention, and simple as it may seem it is entitled to con-

siderable praise in the treatment of fractures of the femur. The use of plasters for attaching the weight to the leg is also an American invention. And I may say right here, that to American surgeons is due the honor for more inventions, and better appliances in the treatment of fractures, than to the surgeons of any country on the face of the globe. As the skin is intact in this case we need not be so careful to observe antiseptic measures as we would were the skin broken. The probabilities are that this man will be one-fourth to one-half inch shorter than he was before this accident, as it is hardly possible that the strong femoral muscles can be drawn out to their full length; and I would say here, that it is always well to thoroughly anaesthetise the patient before trying to do this; for the double purpose of relieving the pain, and relaxing the muscle. There are always three things necessary in the treatment of fractures of the femur, viz: Extension and counter-extension, and the holding of the parts in position, or the preventing of the foot from becoming everted. The two former indications have been explained to you, and the latter is obtained in various ways; some surgeons lay a sand bag along the outer side of the leg, and to obtain the same result we use the splint, invented by Dr. Frank Hamilton, of New York (an American surgeon, too, by-the-way).

When plasters are applied directly to the skin, the mole-skin plaster should always be used, as the ordinary rubber plaster usually blisters the skin. When plasters are made to encircle a limb, they should be cut, or divided at one or more points, so as not to constrict or strangle the circulation of the limb; and where it can be avoided, plasters should not be put in contact with the maleoli, as they are likely to irritate them. For the left leg I will use a Volkmann's slide, which is a somewhat different apparatus, as you see, and one which I have used a great many times, and with good satisfaction generally. For the first few days a weight of about eight pounds will be heavy enough for this limb; after that it may bear twelve to fifteen pounds, and I have used as high as twenty-eight pounds; however, this is about the extreme, about twelve pounds being the average.

Now as to the bed. The bed for this man should be flat, and hard, a hair mattress being about the best, and he will have to lay on his back for several weeks. I find on examination that besides the fracture of both femurs this man has also a fracture of the clavicle on the right side; and now as the best treatment for a fracture of the clavicle is the recumbent position, on the back, in bed, and as this man is compelled to assume just this position for some time, no other treatment will be required for his fractured clavicle. In cases where more than this is required a compress may be placed on the back between the

scapulæ, and the weight of the shoulders will usually be sufficient to bring the fragments into apposition; if not, bags of shot may be laid on each shoulder to further increase their weight. This man will now be removed to the ward, and those of the students who wish may go to the ward and see the weight and pulleys applied.

FRACTURE OF THE CLAVICLE.

The next case we will show you is that of fracture of the clavicle, and as you are now studying fractures, this is a case that I am very glad to have to show you to-day. As you know, fracture of the clavicle occurs from violence, direct or indirect, and this is one occurring from indirect violence. This man fell from a scaffold yesterday morning, and lay unconscious till last night, when it was found that he had sustained this injury, together with other bruises and contusions about his body. As he stands before you now you will notice some deformity; the left shoulder droops, or hangs lower than the right, and in measuring from the sternal notch to the acromion process on the left side, I find that it measures $9\frac{1}{2}$ inches, and on the right side $10\frac{1}{2}$ inches, and, as you can see, the left shoulder also approaches the median line. This is caused by the fractured ends of the left clavicle slipping past, or overlapping each other. These signs, of themselves, would be sufficient for diagnosis, but besides these we have pain, loss of function, false point of motion, history of the accident, and might, if we tried, be able to elicit crepitus: so you see the diagnosis is easy enough in this case. Now the indications for treatment in this case, as indeed in all cases of fracture of the clavicle, are to raise the shoulder up and draw it backward, which is easiest done by confining the patient to bed on his back, with a compress between his scapulæ. But patients will not always submit to this treatment; so other arrangements must be made. In this case I will make use of Dr. Sayre's apparatus, which is simple, always obtainable, and easy of application. It consists first of a pad in the axilla of the injured side, then sew a strip of adhesive plaster about four inches wide, around the arm, draw the elbow to the side of the chest and backward, by passing the adhesive plaster around the back to the opposite side. Then place the hand of the injured side on the sound shoulder, take another adhesive strip, four inches wide and four feet long, cut a small slit in the centre, place the elbow in the slit in the centre, and pass the two ends up to meet on top of the sound shoulder. The anterior end will cover the forearm of the injured side, and retain the hand of the injured side on the sound shoulder. These strips should act as a sling, to raise the injured shoulder and support it in place. Two skin surfaces should never be allowed to remain in contact, so I will place cotton batting

between the arm and the breast. This constitutes Dr. Sayre's dressing for fractured clavicle. Where you are not prepared with plasters to put on this dressing, you may make a very good substitute by making an ordinary four-tailed bandage with a slit in the centre, in which you will place the elbow; then pass two of the tails around the body, confining the elbow to the side, over a pad in the axilla, pass the two remaining tails up over the sound shoulder, drawing it well up, supporting the injured arm. This makes a very good and a very cheap dressing, and fulfils all of the indications for which such dressings are applied. The clavicle is broken oftener than any other bone in the body, and, as in this case, almost always by indirect violence. The weight of the body at one end and the ground at the other, are usually the two forces acting upon the bone, which fractures at its weakest point, which is usually at the junction of the middle with the outer third. This accident frequently happens to babes and small children, from falling from their carriages and chairs. In children it is not a very formidable accident, as it usually heals kindly.

FISTULA IN ANO.

Through the courtesy of Professor McCann, we have another case to show you. It is one of fistula in ano. We place him at once in the lithotomy position, as you see, and the opening is at once exposed to view. A fistula, as you know, may be complete or incomplete. A complete fistula is one with two openings; one external, and one internal opening into the rectum. An incomplete fistula is one with but a single opening, and it may be either internal or external. I will try to pass a grooved director through this opening. In doing this you should always remember that we frequently fail to find the internal opening, and that this is frequently because we search too high up. As you see, I find the internal opening just inside the sphincter, and this is the location where it is usually found. I will incise the part that lies over the director, which constitutes the operation. The wound will now be dressed with iodoform gauze, and the patient kept quiet in bed for a few days, and an effort made to make the wound heal from the bottom.

FRACTURE OF BOTH FEMURS.

We have one more case to show you to-day; that on which I dressed a fracture of each femur three weeks ago. You see we already have a considerable amount of union here, as the man can roll both legs in either direction. I will now do what I would advise you all to do under like circumstances, viz.: to apply a plaster of Paris dressing. Up until within a year or two ago it was my rule to treat fractures of the femur with plaster of Paris bandage from the beginning, but I have about abandoned that practice here for the reason that

it interferes with making extension, and also because, after plaster is applied, every part of the wound is completely concealed from view, and we cannot readily ascertain the amount of progress being made by the reparative process, or whether the bones remain in apposition or not. For these, together with other reasons, we do not put on a plaster dressing until after slight union has taken place. There are various ways of applying this dressing. The plaster should not come in contact with the skin, and to prevent it we use various articles, as blankets, cotton batting, Canton flannel, or tight-fitting drawers, but for fractures below the knee, I prefer an ordinary stocking. In applying plaster dressings all bony prominences must be carefully protected by a layer or two of cotton batting. The points to be especially protected are the condyles of the femur, the spine of the tibia, and the malleoli. At the point of fracture reinforcements should be made by a few extra wraps of the plaster bandage. In the groin also, where counter-extension is to be made, we must be careful to protect the parts with cotton. We then start at the foot, and apply the bandage smoothly and evenly the entire length of the leg, making extra wraps at the point of fracture.

MEDICAL PROGRESS.

GLYCERINE SUPPOSITORIES.—POLUBINSKY concludes the eccoprotic action of the drug cannot possibly be attributed to anything like its softening or liquefying fecal masses, since (*a*) water, milk, olive oil, and other fluids, when injected into the rectum in similarly small quantities (6 grams or so) fail to excite any motions; (*b*) when injected in such trifling doses, glycerine is rapidly absorbed by the mucous membrane; (*c*) stools occurring after glycerine enemata are usually solid and sausage-shaped—that is, show no signs of liquefaction; (*d*) neither are the masses covered with any watery or slimy layer; (*e*) stools take place within a short time after the administration of glycerine, while the liquefaction process should necessarily require a comparatively long interval. 2. Glycerine undoubtedly causes a local irritation (probably congestion) of the rectal mucous membrane, since (*a*) all patients experience a sensation of warmth or some burning in the rectum; (*b*) there is observed a slight rise of the rectal temperature after the enemata; and (*c*) on a digital exploration during “calls” there are detected fairly strong contractions in the upper portion of the rectum. The drug, however, does not increase the secretion of the rectal mucous membrane. 3. The irritation lasts until a complete absorption of glycerine. Possessing a great absorbability, the substance very rapidly penetrates into the (very rich) lymphatic

vessels of the rectum, and, having disappeared from the latter, ceases to act. Hence it is unable to establish any considerable peristaltic action of the bowel lying higher up from the sigmoid intestine.

1. Best results are obtained from glycerine in cases of fecal accumulation in the rectum and S. Romanum. 2. In cases of fecal stagnation occurring higher up (typhlitis, general intestinal catarrh, etc.) the drug is altogether useless. 3. Glycerine enemata or suppositories are indicated especially (*a*) as a means for “training” the rectum—that is, for exciting regular rectal “calls”—in cases of habitual constipations; (*b*) in cases of constipation caused by fecal accumulation in the large bowel, and depending upon atonic state of the intestinal muscular coat, as occurring most commonly in women after parturition. Since intestinal atony in such patients is usually accompanied by a similar state of the abdominal press, a systematic employment of glycerine enemata must be obviously supplemented by daily abdominal gymnastics and massage, faradization of the abdominal muscles, and intra-rectal galvanization; (*c*) in such cases where the rectum and sigmoid bowel are mechanically compressed by pelvic tumors (including early pregnancy; (*d*) in retroversion of the uterus associated with pressure on the rectum; (*e*) in children suffering from scrofula of a torpid variety; (*f*) in such persons who experience difficulty and pain on defecation because of their feces being very hard, and who accordingly often abstain from stools. Here glycerine proves useful mainly as a local lubricant. 4. On the whole, glycerine enemata should be preferred to suppositories, since the latter (*a*) are more expensive; (*b*) their use is rather uncleanly (they easily melt in hands, etc.); and (*c*) their introduction into the rectum by a finger represents a by far more unpleasant procedure than an injection by means of a syringe. 5. In one group of cases, however, suppositories are to be preferred to enemata. It is the group mentioned (sub. 3*f*) where a relatively slow action is desirable, and where lubricant effects of glycerine are intensified by those of cacao butter.—*London Medical Recorder*, March 20, 1889.

PERIPHERAL NEURITIS DUE TO THE VOMITING OF PREGNANCY.—DR. D. W. WHITFIELD reports the following case in the *London Lancet* of March 30, 1889: Mrs. R., æt. 40, a lady of strictly temperate habits, was delivered of a well-nourished female child at full time on Aug. 7, 1888. This had been her seventh pregnancy. Her previous pregnancies had been unattended with much sickness. During this pregnancy, however, the sickness was troublesome from the first, and it increased as the pregnancy advanced, the skin assuming a most unhealthy, sallow appearance, as if the liver was not acting. She

lost flesh rapidly, but was not confined to her bed until the end of the sixth month, when she had a most severe attack of vomiting, large quantities of bile being vomited up. For about a fortnight hardly anything seemed to be retained, and she became so prostrated that I began to think it would be necessary to induce labor. However, at the end of a fortnight she improved a little, and some water gruel and essence of meat were retained. In another week she was able to sit up a little each day, but still the vomiting never ceased entirely, and until her confinement not a day passed without severe attacks of it. All the usual remedies were tried without much effect. Bismuth seemed to do the most good. She was now able to sit up each day, and was down stairs the day before her confinement. A fortnight previously, however, she felt her legs cold, and found she was losing the use of them; she had to be assisted up and down the stairs. She had no pain—only the feeling of coldness in the legs; she tried to obtain warmth in them by sitting before the fire, but in vain. Prior to this pregnancy she was a little inclined to stoutness, and I think she lost at least 80 pounds in weight. Labor was quite natural, lasting about five hours. The vomiting ceased the day after, and she began to take nourishment. She had no rise of temperature, the lochia were normal, and it was thought she was doing well. However, after the fourth day she complained of her legs feeling numb, and a few days afterwards of severe pains in them and of "pins-and-needles" in the hands, a burning sensation in the palms, and pains up the arms. She could move her legs slightly in bed, and the wrists did not drop until the twelfth day after confinement. On the thirteenth day we got her out of bed, and it was then I saw the extensive nature of the disease. Dr. Dreschfeld saw her with me on this date, when we found she had almost lost the entire use of both arms and legs. She was unable to bear the slightest weight on her legs, and had difficulty in crossing one over the other. The patellar and other reflexes were absent; both feet were extended and the toes flexed; the hands were dropped, the wrist and fingers were flexed, and she had no power to extend them. She had difficulty in raising herself in bed, and complained of a peculiar numb feeling around the lower part of the abdomen and epigastric region. The breathing fortunately was unaffected. There was pain on pressure over the main nerve trunks in both arms and legs. The cutaneous sensibility varied in different places—increased in some parts, diminished in others. We gave her liq. strychniæ, and employed massage, and in about a week she began to improve. The improvement has been slow but continuous, and at the present time, the arms, forearms, thighs, and trunk are almost well, but the hands, legs, and feet are not.

She cannot bear any weight on the feet as yet, although she can flex them and move them about more freely, and power is certainly returning gradually.

Remarks.—Of course peripheral neuritis may come on during any wasting disease, and very rarely after a confinement; but I am not aware of any case having been described which has been due to excessive vomiting during pregnancy. The question is, whether, should the symptoms show themselves during an excessively sick pregnancy, it would not be a sufficient reason for inducing premature labor. In this case the early symptoms were extreme coldness of the lower limbs from the hips downwards, with partial loss of power, followed by a feeling of numbness.

ON THE RELATIONS BETWEEN CHOREA MINOR AND POLYARTHRITIS RHEUMATICA, AND ENDOCARDITIS.—(*Wiener Med. Blätter*, 1888, 41 and 42.) HEGGE (Greifswald) says: It is universally admitted that chorea occurs in connection with polyarthritis and endocarditis; but the supposition that chorea and polyarthritis rheumatica and endocarditis always go together, so that a chorea without a rheumatic affection is unknown, is far from correct. Hegge still adheres to his opinion that a connection between chorea and endocarditis and acute rheumatism of the joints cannot be recognized as universally coincident, and that, in a great majority of chorea cases, the coexistence of heart disease is wanting. Also the publication by Brieger shows that the simultaneous occurrence of both diseases is possible only and really happens. The statements of Hegge show that in the clinic of Greifswald, during the past years, in a large number of chorea cases, the coexistence of rheumatic affections and endocarditis has often been observed. Five cases are reported. The first one recalls the case published by Brieger (*Berl. Klin. Woch.*, 1886, No 10). The second case had often suffered from rheumatism of the joints for a year. At the time of the chorea no palpitation existed, but there was a distinct systolic murmur at the apex, and also a second impure sound. In the third case chorea is said to have been caused by acute rheumatism of the joints which had existed two years before, was entirely cured and showed no tendency to relapse. In the fourth case, during the chorea, an insufficiency of the mitral valves was proven, whilst during the previous polyclinic treatment heart disease had not been found. The fifth case shows a patient who had been treated for chorea three years before, when an insufficiency and stenosis of the mitral valves was noted; the patient finally succumbed to a renewed attack of rheumatism of the joints and of compensatory disturbances. The post-mortem proved the heart disease. Thus these reports also show that chorea may occur in the course of infectious diseases, and that

of the latter polyarthritis rheumatica causes it the most frequently, but that not every chorea must have this "rheumatic diathesis," and even that this occurs only in a minority of cases. At any rate, a chorea must not be ascribed to a rheumatic affection which may have existed years before. Nor is the etiology of chorea uniform.—*Centralblatt für Klinische Medizin*, 1889, No. 13.

ON GASTRITIS MEMBRANACEA AND DIPHTHERIA.—(*Virchow's Archiv*, vol. cxlii, 2.) SMIRNOW had occasion to investigate six cases of so-called diphtheria of the stomach, in which the disease had developed immediately after diphtheria of the throat, and had been regarded as a continuation of the latter. In four cases, however, he found only a more or less considerable hyperæmia and extravasation without much cellular infiltration, a more or less extensive desquamation of the glandular epithelium (which had, however, retained its normal qualities), and membranes that could be regarded only as fibrinous, muco-fibrinous and fibrino-purulent. Furthermore, the connection between the membranes and the underlying tissue was everywhere such that the boundary line between them remained for the most part distinctly visible.

The author thinks that, in view of these anatomical conditions, the cases should be called fibrinous inflammation rather than diphtheria proper. In the two other cases there existed acute changes of a diphtheritic character, especially in the epithelium of the glands, such as in diphtheria is known as hyaline degeneration. There was enlargement of the cells, disappearance of the nuclei, and transformation of the cells into glittering homogeneous clots which subsequently melted together and formed the framework of the membrane; and combined with this there was necrosis of the connective tissue of the mucosa itself, so that there could be no doubt but that the disease was a genuine diphtheria, though only in its incipient stages.

From the investigation of the last two cases the author establishes the course of the changes in genuine diphtheria, in opposition to Oertel, as follows: 1. That the process does not begin with an inflammation, but with a necrosis of the pre-formed tissue which takes place with the formation of hyaline products. 2. These products furnish the principal material for the development of the membranes in the first stage. 3. Where inflammatory changes were observed in diphtheria of the throat, it was secondary to the degeneration and belonged to the period of reaction.—*Centralblatt für Klinische Medizin*, 1889, No. 13.

ON INTESTINO-PERITONEAL SEPTICÆMIA.—VERCHÈRE (*Revue de Chir.*, 1888, No. 7), justly declares that the name peritonitis is still wrongly used, and that under it, often, diseases are com-

prised which ought to be assigned an independent position. Among these he counts a complex of symptoms often observed after penetrating injuries to the abdomen, and after laparotomies, which consist of meteorism, more or less complete constipation, vomiting of gall or feces with normal temperature and small pulse. Such cases he would like to designate as intestino-peritoneal septicæmia. The post-mortem in cases with the above symptoms does not show any traces of peritonitis, and the symptoms mentioned are very similar to those observed in strangulation (aside from the circumstance that the course of the latter is generally much more rapid). The author supposes a pseudo-strangulation to be the cause of the disease under discussion, which occurs in injuries to the peritoneum by superficial adhesion of the serous surfaces, eventually also by rupture of a meteorically distended intestine. Death actually ensues from sepsis in consequence of resorption of the substances retained in the intestines, the resorption taking place directly from the mucous membrane, or from the peritoneum, after the intestinal walls have become permeable. According to Verchère treatment ought to be symptomatic. In this respect he distinguishes between the affections just mentioned and the genuine, for which he advocates the most active therapeutic measures.—*Centralblatt für Chirurgie*, 1889, No. 13.

HOW DOES SUSPENSION ACT IN LOCOMOTOR ATAXY?—DR. JULIUS ALTHAUS, in a letter to the *London Lancet*, says: In your journal of March 30, there is an account of a discussion which took place at a recent meeting of the Paris Society of Medicine on the question whether there was any satisfactory explanation of the results obtained in tabes by suspension. No plausible explanation, however, appears to have been forthcoming, and I therefore request your insertion of the following lines, in which I will attempt to account for the striking therapeutical effects which are obtained here as elsewhere by the use of suspension in such cases.

1. It has been ascertained that in tabes posterior spinal meningitis habitually accompanies the pathological changes in the nerve tubes of the posterior columns. The pia mater is found congested and thickened at the level of the posterior columns, the spinal fluid being unduly increased, and this change being more pronounced in the dorso-lumbar than in the cervical region of the cord. Now I maintain that the good effects which are sometimes obtained by cauterization of the spine in such cases are rather owing to its revulsive influence on the meningitic process than on the sclerosis of the nerve tubes; and it appears to me highly probable that part of the influence of suspension, by which the spinal cord is efficiently stretched, is owing to the *breaking down of adhesions from chronic meningitis*, thus

allowing a freer transmission of nervous influence along the nerve tubes, more especially those which run on the surface of the posterior columns. This explanation appears to me also to account for the fact that suspension acts better in advanced than in fresh cases of locomotor ataxy. In recent cases there is more tendency to inflammatory irritation, which may be made worse by stretching, just as recent cases of disease of the joints, tendons, ligaments, etc., are improved by rest, and old cases by forcible extension.

2. The morbid process in the posterior columns and nerve roots consists essentially of destruction of the medullary sheath and the axis cylinder of the central nerve tubes, together with overgrowth of the interstitial connective tissue or neuroglia which cements the nerve fibres. The neuroglia, from being originally soft and yielding, gradually, as the disease progresses, loses its cells and nuclei, becomes firm, hard, and fibrous, and is liable to cicatricial shrinking. The gradual contraction of this tissue causes compression and squeezing of the central nerve tubes, and thus serves to impair their nutrition and conductivity. Now it seems to me allowable to assume that, by the process of stretching the spinal cord, *the overgrown and unduly hardened neuroglia may be loosened and broken down*, with the effect that those nerve tubes which have, to some extent, survived the sclerotic process are freed from compression, become better nourished, and may thus be enabled to transmit the nervous influence more efficiently than before. Apart from this, however, I have come to the conclusion that suspension has, in a number of cases, a beneficial influence on the medulla oblongata, as it stimulates the centres for vaso-motor and cardiac action and for digestion. In several patients whom I have submitted to this treatment, I have noticed that the pulse, which was unduly quick and of low tension before they were suspended, fell by six or eight beats, and acquired more tension after they had been taken down. In a large majority of my cases the appetite and digestion have improved, and mental depression has been lessened or removed.

The forms of nervous disease for which my personal experience leads me to think that suspension is applicable are the following: 1. Locomotor ataxy in the second stage. 2. Paralysis agitans. 3. Spastic spinal paralysis. 4. Amyotrophic lateral sclerosis. 5. Functional nerve prostration, more especially where there is feeble action of the heart; loss of appetite; and severe mental depression.

SYPHILITIC FEVER RESEMBLING TERTIAN AGUE.—DR. SIDNEY PHILLIPS, at a recent meeting of the Medical Society of London, reported the following case: A woman, æt. 27, a cabman's wife, with a healthy previous history,

married in 1879; six months later her hair commenced to fall out, she had ulceration of the tongue and sore throat. Her first three pregnancies ended in miscarriages, she then bore four healthy children, and these were followed by another miscarriage. One of the children had died of whooping-cough, the others remained well. The husband had had syphilis six months before marriage, but the wife had not shown evidence of primary sore. In May, 1888, she was attacked with fever, accompanied by shivering and sweating, the attacks at first recurred every day and then on alternate days. Ten days after her admission to hospital quinine was administered in 2-grain doses three times a day, and then 5 grains were given before the expected pyrexial attack. This at first checked the height of the temperature curve, but afterwards lost its effect, and an increased dose did not improve matters. At length iodide of potassium and mercury were given, which not only reduced the temperature, but also relieved the distressing headache and vomiting which had been present. The differential diagnosis from Hodgkin's disease, typhoid fever, tuberculosis, ulcerative endocarditis, pyæmia, and malaria was discussed. The question whether the pyrexia was associated with a local syphilitic lesion was raised, but no localizing evidence could be obtained. Erythema nodosum was present, and apart from syphilis it was rare to find this accompanied by fever. John Hunter and Fournier had described cases of syphilitic fever similar to that brought forward, but none so late as the ninth year after infection. These rare varieties of specific tertian fever occurred usually in females; the long duration of the pyrexia (eight months) was also a matter of interest.—*Lancet*, April 13, 1889.

A CHEMICAL VACCINE FOR CHOLERA.—DR. YVERT has submitted to the Academy an interesting treatise: "A new curative and prophylactic treatment for Asiatic cholera. Bichloride of mercury considered as an anti-cholera vaccine." The author says: "I have had, during my recent stay in Tonkin, occasion to observe and treat a large number of cases of Asiatic cholera. The mortality in this part of Asia averages as in Europe 66 per cent. Of forty-five patients whom I treated with bichloride of mercury in doses varying between 0.02 and 0.04 gr. within twenty-four hours, I lost only nine *i.e.*, about 20 per cent. As this result proved to me that the mercury had a decided effect upon the pathogenic agent of the disease, I used it prophylactically for patients who had recently arrived in a region infected with cholera. Of those who were thus treated not one was taken with the disease."

M. Léon Cotin, in presenting the above memorial to the Academy, says: "This new treatment is not a mere fancy; the author who

was the medical chief of a post in Tonkin invaded with cholera, claiming not only to have cured, but to have prevented the infection by the administering of the liqueur van Swieten, the Academy will doubtless agree with me that this work merits an especial investigation, and will order its reference to the committee on epidemics." *Journal d'Hygiène*, Vol. xiv, No. 646.

ANTIPIRYN IN LABOR.—DR. ERMANN PINZANI recently made a communication to the Società Medico-Chirurgica di Bologna, in which he gave an account of some experiments he had made with the view of ascertaining the effect of antipyrin on the strength of the uterine contractions in labor. Two series of experiments were made. In five cases he simply kept his hand on the woman's abdomen for some hours, and noted the condition of the uterus before and after the administration of the drug. In eight other cases (on which he made in all twenty-three experiments) he passed an india-rubber ball, first disinfected, and then filled with a watery solution of corrosive sublimate, into the uterus; this he connected with a manometer, which gave him an accurate gauge of the pressure exerted by uterine contractions on the fluid in the ball. Dr. Pinzani was careful to exclude irritation of the uterus by the foreign body as a source of fallacy by previously warming the fluid in the ball to the temperature of the body, and by waiting for some time after its introduction before making observations. In the first set of experiments, 3-gram doses of antipyrin were given by the mouth; in the second, the doses were from one to two grams. Dr. Pinzani came to the conclusion that antipyrin relieves the pains of labor simply by lessening the force of the uterine contractions. The effect of the drug showed itself in about two hours after hypodermic injection, and four or five after administration by the mouth. He noticed that infants suckled by women who had had antipyrin given them during labor were apt to suffer from diarrhoea. Dr. Pinzani's verdict is, therefore, decidedly against the use of antipyrin in midwifery practice. — *The British Medical Journal*, March 9, 1889.

HEPATIC ABSCESS BURSTING INTO THE PERICARDIUM.—DR. JOAQUIN L. JACOBSEN, of Havana, reports a case in which an abscess of the liver, which was not recognized during life, was found after death to have burst into the pericardium. The complication is so rare that Dr. Jacobsen has been able to find only ten cases previously recorded. The patient was a white man, æt. 39, who had been a heavy drinker, and had suffered from malaria. He had been troubled for about a year with dyspeptic symptoms. He was pale and slightly jaundiced, and had lost flesh. Both the liver and the spleen were enlarged, and there was some tympanites. He

complained of constant pain, sometimes referred to the epigastrium, sometimes to other parts of the abdomen. Percussion in the epigastric region caused a little pain, but gave a normally resonant note. He was treated with purgatives and alkalis, and a blister to the epigastrium. The enlargement in the region of the liver increased, but no fluctuation could be detected, and there were no signs of adhesion. Symptoms of intestinal obstruction came on soon afterwards, with marked tympanites and dyspnoea, and three days after the commencement of this new phase of his illness the patient died. At the necropsy the lungs were found contracted and pushed towards the posterior and upper part of the thorax; the parietal layer of the diaphragmatic pleura was thickened and congested; the pericardium, which was also thickened, contained a large amount of sero-purulent fluid, dark-yellow in color; the outer surface of the heart, which was rough and granular, was of the same color. At the lower part of the pericardium, slightly to the left of the middle line, there was an opening with ragged edges, about four centimetres in diameter, passing through the diaphragm and communicating with an irregular opening in the posterior part of the convex surface of the left lobe of the liver. For some distance round this opening there were firm adhesions to the diaphragm. The liver was enlarged and somewhat hardened; its right lobe was congested, and in the left there was a large cavity measuring 12 centimetres in the transverse by 10 in the vertical and antero-posterior diameters, and full of yellow pus. The spleen, which was enlarged and softened, presented two large milky-looking patches on its outer surface. The gastro-intestinal mucous membrane was thickened and injected. All the other organs were healthy. Dr. Jacobsen points out that the abscess was in the posterior part of the liver, leaving a considerable portion of the front part of the left lobe untouched, while the symptoms did not clearly indicate any affection of the liver beyond what was consistent with the patient's gastro-intestinal disorder and alcoholic antecedents. Exploratory puncture could hardly have been successful even if it had been thought justifiable. — *British Med. Jour.*, March 16, 1889.

CURE OF A CASE OF MORBUS BASEDOWII THROUGH IMPROVEMENT OF A NOSE TROUBLE.—HOPMAN (*Berl. Klin. Wochenschrift*, 1888, No. 42), found in a patient suffering from rhinopharyngitis sicca with extensive crust formations in the nose and pharynx, exophthalmos, especially on the right side, considerable stenocardia and general feeling of weakness, which symptoms led him to suppose an incomplete form of morbus basedowii. Through appropriate treatment of the nose trouble the morbus basedowii was cured. — *Centralblatt für Klinische Medizin*, 1889, No. 13.

ETIOLOGY OF PULMONARY PHTHISIS.

The recent comments in THE JOURNAL concerning the best climate for consumptive patients, and the necessity for careful discrimination in regard to the extent and stage of progress of the pulmonary disease, as well as to the special qualities of climate, have called forth a letter from DR. HENRY B. BAKER, Secretary of the Michigan State Board of Health, which will be found in this number of THE JOURNAL under the head of "Domestic Correspondence." The letter calls our attention to his paper read in the Section of Climatology and Demography of the International Medical Congress in Washington, D. C., 1887, in which he claims that dry cold air exerts a controlling influence in the production of all the inflammatory affections of the respiratory passages and parenchyma of the lungs, including pulmonary phthisis.

The facts, statistics and diagrams contained in his paper constitute a valuable contribution, and so far as they relate to the prevalence of coryza, influenza, bronchitis and pneumonia, chiefly during the coldest part of the year, they are in entire harmony with the facts and deductions contained in the valuable monograph on "The Climate of the United States and its Influence on the Prevalence of Diseases," by Samuel Forrey, and in the large work of Daniel Drake published near the middle of the present century, and works of many other writers. While the accumulation of facts abundantly prove that in this country more deaths result from pneumonia and the strictly inflamma-

tory affections of the air passages, annually, during the months of January, February, March and April, than in all the other months of the year, the same rule does not apply, however, except in a very limited degree, to pulmonary phthisis. This is proved by the tables adduced by Dr. Baker himself. His table 10 gives the average deaths per week from phthisis in London for thirty years, from 1845 to 1874, showing the highest average in any one month 162, for April, and the lowest 132, for September; and his table 11, showing the average percentage of sickness from phthisis in Michigan for nine years, from 1878-1886, gives the highest average for any one month 70, in April, and the lowest 61, in August. Doubtless, if the diagnosis between true tubercular phthisis and chronic interstitial pneumonia (catarrhal phthisis) had been made, which was not the case in these tables, the comparatively small excess for the months of March and April would have been found resulting entirely from the latter form of disease, leaving the true tubercular disease very equally distributed throughout the year. Another fact fully established is, that tuberculosis originates far more frequently among those classes in any community that are most confined within doors, in the most damp and badly ventilated dwellings, instead of among those most exposed to cold dry air. Dr. Henry I. Bowditch, many years since, established, by a careful examination of the records of mortality from phthisis for a series of years in the various school districts of Massachusetts, the fact that the highest ratio of its prevalence and fatality was uniformly in the districts having most dampness or water in the surface soil, and consequently the greatest amount of aqueous vapor in the atmosphere.

The topic of most particular interest in the paper by Dr. Baker, is, his theory of the production of bronchitis, pneumonia, phthisis, etc., by the inhalation of very cold and dry air. He states "that the breathing of cold air (which is always dry air, because cold air cannot contain much moisture) dries the throat and air-passages, that this leaves in the throat and air-passages salts of the blood, which do not evaporate with the moisture; that the albuminous parts of the blood, which do not pass out of the blood-vessels under other circumstances, do pass out whenever the salts accumulate greatly in the fluid which

naturally moistens the throat and air-passages. Therefore, whenever a person has breathed unusually cold dry air until that fluid, because of its evaporation, contains much salt, the albuminous part of the blood comes out in the throat or lungs wherever the salty fluid is. Whenever this exudation occurs there is then a chance for the *bacillus tuberculosis* to lodge and multiply, because it is there kept in a nutritive solution at the temperature of the body."

He claims that all the diseases named are controlled by the temperature and dryness of the atmosphere, and in the manner just indicated. How can this explanation be reconciled with the fact that the highest ratio of phthisis to the population is in the North-Eastern and Middle States, and the highest ratio of pneumonia is on the lower part of the Atlantic Slope between the Delaware and Savannah, and in the middle and northern part of the Mississippi Valley, with deep, moist alluvial soil, and atmospheric moisture above the average for the whole country? Again, if it is cold and *dry* air that favors the production of pneumonia and phthisis, why does the first reach its climax in February and March, and the last in March and April, the three most changeable and *wet* months of the year?

PHAGOCYTES.

DR. WILLIAM OSLER, in his interesting address before the Society of the Alumni of Bellevue Hospital, April 3, 1889,¹ gave an excellent summary of what is at present known concerning the active functions of those normal protoplasmic bodies, termed colorless corpuscles, migrating cells, leucocytes, etc. Since Metschnikoff clearly demonstrated the fact that the colorless corpuscles of the blood were not only capable of amœboid movements, but also of attacking and enveloping foreign bodies in the blood and tissues, a large number of active investigators in Europe and America have studied the subject with more or less success. And all agree in stating that these cells are, throughout the healthy structures of the body, actively engaged in enveloping and removing minute particles whether derived from the disintegration of tissue or introduced from without.

From their exhibition of this capacity to de-

vour and remove obstructions and foreign particles, they have been called *phagocytes*. Dr. Osler says they are met with: "1. As the colorless corpuscles of blood and mucus. 2. The connective-tissue cells, free and fixed, within the connective-tissue proper, or forming the supporting framework of the solid organs. 3. Cells of the spleen, bone marrow, and lymph glands. 4. The vascular and lymphatic endothelium. 5. The alveolar epithelium of the lungs." Metschnikoff regards the function of all these phagocytic cells, whether in the blood or in the several structures, as a property derived from the primitive unicellular organism; and attempts to show a genetic relation between the free living rhizopods and the cells of the middle germinal layer of the higher animals.

The lecturer first gives the principal facts established by a number of able investigators relating to the work done by the phagocytes in the physiological processes of nutrition and disintegration or metabolism, and shows conclusively that they exercise important functions throughout the lifetime of the animal. He says: "Not only in the early steps in the development of the blastoderm do we see them actively at work, but in the various stages of development, and in the mature body we have seen that in the lungs, in the intestines, and in the blood-making organs they have most essential functions." He next presents, in a clear and impartial manner, what has been ascertained concerning the action of the phagocytes on such microorganisms or parasites as may invade the living body. He gives the results of Metschnikoff's observations concerning the action of leucocytes in destroying the anthrax bacilli, the microorganism of erysipelas, the spirillum of relapsing fever, and the bacillus tuberculosis. He gives also the observations of Baumgarten and Hess in relation to the same microorganism, and those of Ribbert and Hess in regard to their action on the staphylococcus pyogenes aureus when injected into the lungs of rabbits; and those of Christmas-Direcknick-Holmfeld, Richard, Marchiafava and Celli, Golgi, Bitter, Nuttall, Sternberg, Councilman, James, Shattuck, and his own. Three or four of the last named have devoted much time to the study of the hæmatozoa of Laveran, as presented in the blood of patients affected with malarial fever and their relation to leucocytes. All the investiga-

¹New York Medical Journal. April 13, 1889.

tors who have carefully studied the subject, agree that the cells in the blood and tissues included under the head of leucocytes are found in various parts, containing within themselves more or less of the debris from disintegrating red corpuscles, necrotic tissue, and various microorganisms, and may, therefore, be regarded as natural scavengers; they do not all agree in regard to their true phagocytic character.

For while Metschnikoff, Laehr and Ribbert would represent them as an army of warriors, ever ready to attack and devour every microorganism that ventures to invade the living body, thereby making the living body a perpetual battlefield, in which the army of phagocytes are waging, with varying degrees of success, an exterminating contest with the hosts of pathogenic germs that are perseveringly striving to enter their citadel; Baumgarten, Hess, Bitter and Nuttall, directly deny their active phagocystic character, and claim that they are simple scavengers aiding in the removal of the debris resulting from either disintegrating structure elements or microorganisms already dead, or foreign particles of any kind. With strict impartiality Dr. Osler closes his excellent lecture with the following paragraph:

"To conclude: While phagocytosis is a widespread and important physiological process throughout the animal kingdom, and while it undoubtedly plays a most important part in many pathological conditions, the question of an active destructive warfare waged by the body cells against the microorganisms of disease must still be considered an open one."

ATROPINE AS A REMEDY FOR SHOCK.

Under this head DR. FRANK C. BRESSLER, of Baltimore, has a brief communication in the *Therapeutic Gazette* for April, 1889, in which he refers the primary seat of shock to the nervous centers in the medulla oblongata. He claims that shock is not only a depression of the circulation, but in every case involves the cardiac, respiratory, vaso-motor and secretory centers, so far as they exist in the medulla oblongata, and consists in a sudden molecular disturbance in those centers of greater or less severity. It is not claimed that all these centers are equally disturbed in every case of shock. On the contrary, in some

cases the cardiac and vaso-motor functions are chiefly affected, and in others the respiratory suffer most, as it did in the case related by Dr. Bressler; and in choosing remedies we should be guided by the special predominating feature of each case. The correctness of the claim that *all* cases of shock have their primary seat in the medulla oblongata admits of some doubt. Cases of shock derived from blows or severe injuries in the epigastric region, especially, have been characterized by such extreme depression of the vaso-motor influence over the circulation, while the respiratory and mental functions were much less disturbed, as to suggest the thought that the primary seat of molecular disturbance was in the semi-lunar and other abdominal ganglia of the sympathetic system of nerves, and only reached the cerebro-spinal centers secondarily through the connecting links with those centers.

Granting the correctness of the position that the alarming condition recognized as *shock*, whether produced by mental or physical influences, consists in a direct depression or impairment of the function of one or more of the important nervous centers, in choosing remedies it is of much practical importance that we keep in mind two facts; *a.* that a large percentage of cases of shock have recovered without any remedies, except fresh air and rest, and many more have done so in opposition to the injudicious remedies used; and *b.* that when medicines are required they should be such as are capable of increasing either nerve force or nerve sensibility, or both, and not mere anæsthetics that while quieting restlessness, actually diminish both sensibility and activity in the nerve centers. But this distinction is entirely lost sight of by the people and a large proportion of the profession, as we see in the almost universal resort to alcoholic liquids as the first, and in many cases the only remedies in such cases. And yet no fact is better established than that alcohol is as direct an anæsthetic as is chloroform or ether, and as certainly diminishes both the sensibility and activity of the nerve centres, even to the degree of entire paralysis if the administration is continued sufficiently active. As an illustration of this general tendency to confound anæsthetics with nerve tonics, Dr. Bressler himself commenced the treatment of the interesting case he relates by administering brandy both by hypodermic injection and by the mouth,

but finding "no improvement," and the "breathing becoming shallower," he abandoned its further use, and his patient was given $\frac{1}{80}$ gr. of sulphate of atropine by hypodermic injection and the same was repeated five minutes later, and in less than five minutes more the "breathing began to get freer, the pulse became fuller," and the improvement continued until all alarming symptoms had disappeared. Had he continued to multiply the doses of brandy, its anæsthetic effect might have extinguished what remaining respiratory nerve force the patient had, and both friends and physician would have excused the death on the supposition that they had not been able to commence the use of the remedy early enough; as has often been done in times past. We are fully satisfied that the class of remedies to which atropine, digitaline, strychnine, caffein, theine, etc., belong, afford us the most efficient means for relieving shock, and all instances of sudden depression of the respiratory, cardiac, and vasomotor nerve functions. When not readily administered by the mouth, they can be used efficiently by hypodermic injection or by rectal enema suspended in either water or milk as warm as the rectum will tolerate.

MEDICAL PROGRESS IN AMERICA.

During this eventful week we celebrate the Centennial of our Republic under its present constitution. It seems appropriate at such a time to consider briefly the progress of medicine in our country during these eventful years. It should be remembered that during the first fifty years in the history of the infant Colonies, the question paramount to all others was simply that of *survival*; that during the century that preceded the present, these Colonies were confronted by the two most powerful nations beyond the sea and by their savage allies lurking in ambush behind us, in the adjustment of the great questions of *domain*, of *tribute* and of *franchise*. While blood was flowing, as the price of a free Republic, the sons of America had little time for other thought. In the beginning of the present century, when it was written of us: "In the four quarters of the globe who reads an American book? or goes to an American play? or looks at an American picture or statue? What does the world yet owe to American physicians and surgeons?" much as they might appreciate

books and the stage, the fine arts and the culture of men, our people had been in no condition, until the dawn of the present century, to discover to the world their real purpose and their power. At that date few of our young men were possessed of the means and the leisure to pursue their professional studies in foreign schools, much as they might desire to do so. The church and the common school, during all these years, had stood side by side, and the establishment of a free and permanent Government gave the opportunity for the wonderful developments which were to follow. During these hundred years, while fifty millions of people have been added to our population, and while our material advancement has been without a parallel, it is interesting to note with what success the medical profession has been able to meet the immense requirements laid upon it.

A century ago, the University of Pennsylvania founded in 1765, and Harvard University, organized in 1782, represented the only medical colleges upon this Continent. In 1797 Dartmouth was added to the list, and in 1807, the New York College of Physicians and Surgeons was founded. From these beginnings, there have come to be at this date one hundred and four regularly organized medical colleges—exclusive of all others in any way allied to specialties or pathies.

The progressive character of our schools is manifest in the more and more general adoption of graded courses of instruction, in their preliminary requirements, in their lengthened terms of study, and in the requirement of full courses of clinical instruction, both in laboratories and in hospitals. The students who graduate from our colleges now number over four thousand annually—and yet a careful examination reveals the fact, that this number only equals the demand.

During the century the creation of hospitals has been one of our most beneficent works—until now not a city of any note, not a populous county of any State, but has ample provision for its deserving poor and its sick people.

During the century, medical journalism in America has been created. It has already accomplished a vast work for our profession. Much yet remains to be done, and it has before it vast possibilities and unlimited field for improvement. American medical text-books are witness and a credit to American authors.

In answering the question, "What does the world yet owe to American Physicians and Surgeons?" we may truthfully answer, that they offer to their countrymen a skill and a success in medicine and surgery that is unsurpassed. The records of the recent *war* have given the surgeons of our armies a record of such results on the field, in the camp and in the hospital as had never been achieved before, and it would be injustice to our physicians to accord to them a less worthy record. During the century America has made two contributions to the profession, which may be best stated in the language of a distinguished English writer, Prof. G. T. Bettany.

Writing upon the history of ovariectomy, after stating that John Belle, in Edinburgh, in 1794, had dwelt with much force upon the practicability of removing ovarian tumors by operation, Prof. Bettany says: "It was reserved, however, for a pupil of his, Ephraim McDowell, from Virginia, to perform the first modern operation of ovariectomy for disease.

"He settled in practice in Kentucky in 1795, and in 1809 carried into effect this novel operation upon a middle-aged woman, who survived to complete her seventy-eighth year, in 1841. Thus an American had the glory of first boldly starting in the new path."

Again, writing with reference to the introduction of ether as an anæsthetic, without discussion of the priority of its use by American dentists, and of its successful use by them in September, 1846, he writes that "in October following it was used in an important operation by Dr. J. C. Warren, at the Massachusetts General Hospital. The news arrived in England before the end of 1846, and on December 19th James Robinson, a dentist on Gower Street, London, was the first to operate under ether in this country, for the removal of a tooth. On December 21st Robert Liston employed it most successfully at University College Hospital on an amputation of a thigh. . . . Its general adoption followed in the first few months of 1847."

When we consider the unparalleled growth of the Nation, the absence of educational institutions at the beginning, the cost of their development, and the difficulties to be encountered, while we are deeply sensible that much more might have been done, we heartily congratulate the medical profession that during the century so much has been accomplished and that our countrymen have done their work so well.

EDITORIAL NOTES.

THE AMERICAN SURGICAL ASSOCIATION will hold its next annual meeting in Washington, May 14, 15, and 16, 1889. David W. Cheever, M.D., of Boston, President, and J. R. Weist, M.D., Richmond, Ind., Secretary.

YELLOW FEVER.—A pretty well authenticated case of yellow fever has been reported at Sanford, 120 miles south of Jacksonville, Florida, that terminated fatally on the 20th of April, 1889. The victim was a Mrs. Dumont, the wife of a baker and keeper of a boarding-house. Active measures are being taken to prevent its spread under the direction of Dr. Daniel, President of the Florida State Board of Health. The sanitary condition of Jacksonville is reported as good.

MEDICAL MISSIONARY WANTED.—A competent physician and surgeon is desired, by the Secretaries of the Missionary Society of the Methodist Episcopal Church, to take a position as physician and surgeon to the Jeho Silver Mining Company, in North China. It is desired that he should be a member of the Methodist Episcopal Church, who is willing to devote himself to medical missionary work in the Chinese Empire. For one who is thus disposed an opening of unusual promise for successful work is here presented. Please address Corresponding Secretaries, Mission Rooms, 805 Broadway, New York.

INCONTINENCE OF URINE IN CHILDREN.—Dr. Simon Baruch, in the *Archives of Pediatrics*, April, 1889, claims considerable success in the treatment of this frequent and annoying affection with belladonna or atropine. To children from 6 to 10 years of age he gives $\frac{1}{8}$ gr. of atropine about 4 o'clock P.M., and repeats it at bed-time, unless at that time the pupils are well dilated. He deems it necessary for success in the treatment that the child be sufficiently under the influence of the medicine to have the pupils dilated during the hours of sleep.

ASSOCIATION NEWS.

American Medical Association. Fortieth Annual Meeting.

Laryngological and Otological Section of American Medical Association.

The officers of this Section can assure the profession of a full and profitable session, as there

have already been promised over thirty papers. The following is but a partial list of the contributors. A revised list will be published soon:

Bryson Delavan, M.D.; C. H. Knight, M.D.; Lawrence Trumbull, M.D.; Holbrook Curtis, M.D.; Chas. H. Knight, M.D.; C. E. Bean, M.D.; Geo. A. Richards, M.D.; Chas. Denison, M.D.; S. S. Bishop, M.D.; A. B. Thrasher, M.D.; Carl Seiler, M.D.; Chas. E. Sajous, M.D.; Hal. Foster, M.D.; John E. Logan, M.D.; F. Whitehall Hinkel, M.D.; W. C. Richardson, M.D.; F. O. Stockton, M.D.; Lenox Browne, London.

The following have signified their intention of furnishing papers if possible for them to do so:

E. F. Shurley, M.D.; E. Holden, M.D.; J. N. Mackenzie, M.D.; John Porter, M.D.

The programme will be carefully arranged and a definite time allowed for each paper, so that no time need be wasted. All titles should be sent to the Secretary before the 14th day of May.

E. FLETCHER INGALS, M.D., Sec'y.,
70 State St., Chicago.

W. H. DALY, M.D., President.

Section on State Medicine.

The following additional papers have been prepared for the Section on State Medicine:

"Notes on the Progress of Leprosy," Dr. Benjamin Lee, Philadelphia, Pa.

"Disposal of House Refuse," Dr. Alfred L. Carroll, New York, N. Y.

"Modern Sanitary Conditions," George E. Waring, Jr., Newport, R. I.

"Ranch Life in Texas for Consumptives," Dr. J. R. Briggs, Dallas, Tex.

"The Benefits of Sanitation Applied to Obstetric and Gynecological Surgery," Dr. T. A. Ashby, Baltimore, Md.

"Report of the Standing Committee on Meteorological Conditions," Dr. N. S. Davis, Chairman.

S. T. ARMSTRONG, Sec'y of Section,

U. S. Marine Hospital Service, New York.

J. BERRIEN LINDSLEY, Chairman.

SOCIETY PROCEEDINGS.

Medical Society of the District of Columbia.

Stated Meeting, December 19, 1888.

THE PRESIDENT, THOMAS C. SMITH, M.D., IN
THE CHAIR.

DR. MORAN presented for Dr. P. J. Murphy the following pathological specimens:

AN OVARIAN MULTILOCLAR CYST.

Mary G., æt. 20, white, single, native of Va. Admitted Nov. 28, 1888. Puberty at 14. Was well in every respect until fourteen months ago,

when she was confined to bed for several days by severe pain in the lower part of the abdomen. At that time she noticed a swelling in the left side which has increased steadily until the whole abdomen is distended. She has had no pain since the first attack except backache at times. Menses have continued regular and normal to date. Menstruated November 27 to December 2. Slightly constipated. Appetite poor. Nervous. Does not sleep well. Has lost a great deal of flesh.

Examination December 12, under ether. Irregular mass in abdomen, movable, and extending from below the pubes two inches above the umbilicus. This mass was firm, lobulated, and no distinct fluctuation detected. Uterus normal and does not move with the growth. Body of uterus and right ovary could be distinguished per rectum. Left ovary not felt.

December 19. After a consultation of the advisory board the patient was etherized, and an exploratory incision three inches long made in the median line. The tumor was found to be ovarian (left ovary), and the incision was extended to the umbilicus, after attempting to draw off fluid from the growth with a trochar, several vascular adhesions ligated and cut, and one large adhesion to the abdominal wall torn through. The tumor was then turned out of the abdominal cavity, the pedicle ligated with strong silk and severed with scissors. Shock was severe—the patient being pulseless for thirty minutes after the mass was turned out, and the hæmorrhage from adhesions was severe and difficult to control; numerous ligatures of fine catgut were used for this purpose. The bleeding was finally checked, and a drainage tube being inserted, the wound was closed with deep sutures of silk and superficial sutures of catgut. She was put to bed, given $\frac{1}{4}$ grain of morphia hypodermically and reacted well.

CANCER OF THE RECTUM SIMULATING PELVIC CELLULITIS IN ITS PHYSICAL SIGNS.

B. C., æt. 55, white, native of Ireland, applied for admission to the Hospital December 3, 1888, giving the following history: Never married. Had good health until four months ago, when, after standing a great deal on her feet, she experienced pain in the right iliac region. This pain was severe at times, always present, and growing worse. About the time this pain began her bowels commenced to move four or five times a day. Evacuations watery, light colored, and containing mucous strings. Appetite fair. Otherwise healthy. Has been living on toast and "dry food" to check the diarrhœa.

Examination. Patient emaciated. Abdomen flabby and slightly tender to pressure on right side. Uterus prolapsed and immovable. Cervix small, with a "pin hole" external os. Vaginal

roof indurated and a hard mass plainly felt in the sac of Douglas, tender to the touch.

It was thought to be a case of pelvic cellulitis, and intestinal catarrh, and the patient admitted to the Hospital. She was put to bed, given a milk diet, hot douches, and a 5-grain salol pill every four hours. In a few days the diarrhoea ceased and she became constipated.

December 10. A dose of salts given and vomited.

December 11. This was repeated, but the bowels did not move. Enema ordered, but without effect.

December 12. Castor oil capsules containing $\frac{1}{4}$ drop of castor oil given, one every four hours until four were taken.

December 13. Abdomen tympanitic. Patient vomiting frequently. Pulse and temperature normal and abdomen not tender. Had several attacks of colicky pain during the day. Rectal tube passed thirteen inches into rectum and emulsion of turpentine, quinine and glycerine injected. Strychnia given by the mouth.

December 14. To overcome paralysis of the intestine and soften scybalaë the faradic current was used and the rectal tube used for injections every two hours with the patient in the knee-chest position. Water, glycerine and other liquids thus injected regurgitated by the side of the tube when force was used, but some fluid was retained. During the day the patient vomited faecal matter.

December 15. After vomiting stercoraceous matter, she had violent pain for fifteen or twenty minutes, and her strength failed rapidly. The extremities became cold, and the radial pulse extinct. Stimulants and heat were unavailing. A fine trochar passed into the abdomen allowed gas to escape, but did not improve her condition. She died at 12 o'clock of exhaustion and heart failure. She was perfectly conscious to the last, and during the whole course of her illness the temperature was normal, and she had little pain except a few sharp attacks lasting fifteen or twenty minutes.

It was subsequently learned from her sister, that she had been ill for more than a year, having had marked symptoms of stricture of the rectum. These symptoms had been purposely withheld.

The post-mortem was made by my assistant, Dr. W. P. Carr, who had charge of the case, with the following result:

Autopsy four hours after death. Rigor mortis. Body emaciated. Stercoraceous matter running from the mouth. Abdomen greatly distended and tympanitic.

Peritoneal cavity contains some gas, and about a gallon of dirty serum mixed with faecal matter. Intestines adherent to each other, to the omentum and to the abdominal parietes, many of the ad-

hesions being old and very firm. Sigmoid flexure of the rectum, at a point fourteen inches above the anus, attached to the posterior wall of the uterus by a dense cancerous mass; and the intestinal wall thickened and bent at this point so as to cause complete obstruction. Above the obstruction, the whole large intestine distended to a diameter of three inches by semi-fluid faeces, is in a gangrenous condition, and has to be handled with great care to prevent dropping to pieces. This condition most marked at the caecum, where the gut wall has sloughed through in places, allowing faeces to escape into the peritoneal cavity. Spleen, liver, and kidneys, of a light-blue slate color—tough and leathery.

DR. GEORGE WOODRUFF JOHNSTON reported a case of *Fibroid of the Uterus Treated by Electricity*.

DR. J. W. BOVEE read a paper on

THE USE OF ELECTRICITY IN THE TREATMENT OF DISEASES OF THE FEMALE PELVIC ORGANS.

(See p. 505.)

DR. J. R. BROMWELL said he had listened with much interest to the paper and report just read. As there was so much yet to learn regarding the application of electricity in the treatment of diseases peculiar to women, he asked pardon for any criticism he might make in the discussion. In making use of such indefinite terms as "galvanic or faradic current," and failing to measure, by accurate doses, the electricity used in the treatment of his cases, Dr. Bovee's paper was incomplete, and lacking in practical value as a guide to us in the treatment of similar cases hereafter. Positive and definite dosage is as necessary in the electrical treatment of disease as it is in any other method, and unless the intensity of the galvanic current used is accurately measured, by having a reliable milliamperemeter in the circuit, the treatment is uncertain, haphazard and empirical. It may be negative in its results, owing to no current passing, or it may be positively harmful from the unknown strength of the current. He had known patients treated for weeks by a most skillful physician, with one of the most improved batteries, before milliamperemeters were in general use, who thought he was giving his patient the full benefit of electrical treatment, but, upon placing a reliable milliamperemeter in the circuit, found, much to his astonishment, that it failed to register more than 3 or 4 milliamperes, with a minimum resistance. His battery had run down. With the battery in such condition, had he been guided by the number of cells which the patient could bear with comfort, or freedom from severe pain, as to the strength of current to be used in future treatment, and in his next case used a battery more recently charged, incalculable harm might have been the result, three or four cells of a recently charged acid battery giving as strong a current

as a dozen of one almost exhausted. There are few, if any, perfectly constant batteries in the market, all varying more or less, owing to the use to which the battery has been put since charged. There are other reasons, fully as weighty, why something more reliable than the number of cells used is necessary. The resistance offered by the tissues to the passage of the current is never the same in any two patients. The resistance offered by the electrodes varies also. The action of the poles, which are widely different one from the other, the size, shape, and material of the electrodes, as well as where and how they are placed, are subjects worthy of the most careful consideration and study, and should be noted in the record and report of all cases treated by electricity. Any haphazard use of the poles is unscientific, lacking in practical value, and unquestionably harmful, not to mention the perplexity to the operator when improperly used. Englemann, Apostoli and others have laid down such clear and positive rules for the guidance of the gynecologist in the use of electricity, that it would be inexcusable to occupy time by repeating them here.

The enthusiasm of a year ago, when batteries were selling here by the hundred, has calmed down, and electricity is settling down to a more reliable basis as a remedial or curative agent in the hands of the gynecologist. And if we hope for anything of practical value from it, or to place it upon an equal footing with other methods of treatment, or to formulate rules for our guidance in treating other cases, or to arrive at positive scientific conclusions regarding its value, we must work with it scientifically and not empirically, to fool ourselves and tickle the fancy of patients, who may be awed by the display of elaborate and costly apparatus into believing that something wonderful is being done.

Whilst not a cure-all, electricity has its proper place, and that an important one, in the treatment of diseases of women. Fibroids *will* diminish under proper electrical treatment, and thereby in some, if not all cases, do away with the necessity for the use of the knife. Some of their most dangerous symptoms are relieved by electricity; for instance, the troublesome hæmorrhage so often accompanying them. Frequently repeated applications, extending over months or years, are now abandoned for fewer applications, but higher intensities, 150 to 200 milliamperes, by electropuncture into the body of the tumor. The action of electricity upon neoplasms continues for some time after the treatment, consequently there is no need for very frequent applications, when properly applied. One year ago he was very enthusiastic over the results of the electrical treatment of cervical stenosis, but was sorry to say he had changed his mind, owing to all his cases returning to their original condition five or six months after stopping treatment.

To remove indurations and extravasations resulting from pelvic inflammation; to relieve ovarian pain, or, as Engelmann says, engorgement and accompanying pain; as an auxiliary in treating uterine displacements; to relieve some forms of constipation; and in the treatment of hysteroneurosis, electricity had given him good results.

The proper treatment for laceration of the cervix uteri is an operation. He thought, in regard to Dr. Bovee's first or second case, that all the good results secured were obtained by the operation, and not by the electrical treatment. Only a short time ago he operated upon a woman whose health was a perfect wreck, due to a badly lacerated cervix and its accompanying hyperplasia. She is now in perfect health, with no other treatment. There are idiosyncrasies forbidding the use of electricity which cannot be determined beforehand. He had seen a current no stronger than 3 or 4 milliamperes, the negative electrode in the uterus, the positive, a dispersing electrode 4×6 inches, cotton covered, on the abdomen, cause nausea, vertigo, and an inability to walk or stand for some time afterwards. When this condition exists, the only thing to be done is to abandon electricity in that case.

DR. JOS. TABER JOHNSON said he had not intended to speak upon this subject, as he was not yet quite sure what value to place upon electricity in gynecological cases, but would say a few words upon some of the points raised in the very interesting paper of Dr. Bovee. He would endorse all that Dr. Bromwell had so well said in his opening remarks in regard to exact dosage. To say that a patient had simply been treated by electricity was not enough in this day, when so much is known of the value and effect of the various kinds of currents, their strength, quality, quantity, intensity, length of séance, etc.

The treatment of extra-uterine pregnancy was a very large and important subject. It was one of the live and vexed questions now agitating the profession. There existed quite a difference of opinion in minds of equally good men as to the final value of electrolysis in these cases. It was claimed by some that in many of the instances reported as cures by this agent ectopic gestation had never been proven to exist; and abdominal surgeons were slowly coming to the conclusion that in the long run women stood a better chance of ultimate recovery to have their abdomens opened and the entire mass thoroughly and properly removed, than to run the gauntlet of many dangers from the presence of a dead foetus in their bellies for many months, and perhaps for years. In a recent discussion on this subject before the American Gynecological Society Dr. Johnstone, of Kentucky, had compared the foetus and its membranes or placenta killed by electricity to a dynamite cartridge ready to explode on provocation, and to finally destroy the patient by the

slow and exhausting process of ulceration and inflammation, or by the more rapid process of septicæmia.

The case mentioned by Dr. Bovee in his paper was a good illustration for both sides of this question. A distinguished gynecologist had reported it as a success for electrolysis. He thought he had killed the fœtus before the completion of the third month, and had thus saved his patient, but the subsequent history of the lady showed that she had been a terrible sufferer. She had septicæmia for weeks, and finally the bones of a five months' fœtus were with difficulty extracted through the vaginal roof, and very offensive discharges were escaping for a long time. If this patient had been operated on as soon as the diagnosis was made out she would probably have been cured in much less time, and would have suffered much less, and been in much less danger. While he had never operated on a case of this kind and was therefore not in a position to give advice, still he felt quite sure that, in this age, if he were certain of his diagnosis he would operate—if not certain he would resort to electricity, and he thought that was the position the profession would soon come to occupy.

The treatment of uterine fibroids by electricity was also a large subject. Its proper use demanded much knowledge of the subject, and skill in the manipulation of powerful batteries. It was claimed by Engelmann, Cutter, and Martin, in this country, and Apostoli, Keith, and others, in Europe that a few applications of strong currents was all that were required.

A deep puncture of a large fibroid with a properly insulated, sharp-pointed electrode—with a very large dispersing abdominal electrode—and a current of 200 or 250 milliamperes, was recommended. Its repetition was not considered safe oftener than once in a week or ten days, and from six to ten, or even a less number of applications was thought to be sufficient. In these operations accidents have occurred. Indeed one abdominal surgeon stated sometime ago that he had heard of more deaths from the use of electro-puncture than had occurred to him in the performance of pre-vaginal hysterectomy during the year. Many of the cases reported as having been treated by electrolysis he felt sure, from the meagre reports, had not had all the advantage which might follow the use of the skilled and scientific application of this valuable remedy, though, as stated, months had been devoted to it and several hundred applications had been made.

Then again, there are cases we are not yet able to determine beforehand, which not only fail to be benefited by electricity but, as Van de Warker recently pointed out, are actually made worse by it. The tumors are irritated by the repeated shocks, and either grow more rapidly or degenerate into fibro-cystic tumors. As it is uncertain

what tumors would be benefited by electricity he would recommend its use in all fibroids requiring any treatment, and not resort to surgical interference until a reasonable trial had demonstrated its failure.

Very few uterine fibroids of any size had yet been caused to disappear under its influence. The most that enthusiasts claim for it, is that some of their patients have been symptomatically cured. This is a great gain of course, but it cannot be yet successfully shown that the removal of these tumors will not be occasionally demanded in order to save life—or to make life at all endurable.

The author of the paper gave a number of cases of pelvic diseases in women which he thought had been cured by electricity, and yet in nearly all of the cases detailed many other remedies were used conjointly, and in some cervical and perineal lacerations were successfully operated on, so that we are left in doubt as to which remedy we should ascribe the cure. We all share in the hope expressed by the Doctor that electricity may drive the surgeon out of the female pelvis, and that ovaries and tubes heretofore sacrificed to his knife may hereafter be saved by this subtle and mysterious agent, but at present the distinction must be drawn between masses in the pelvis which are the products of inflammation, and collections of pus. Electricity may relieve the former and should be faithfully tried. It may relieve the pain and symptomatically cure the patient, and in many cases greatly benefit and entirely cure them by causing the complete absorption and disappearance of the pelvic mass, but in severe or long-continued chronic cases of pelvic abscess or pyo-salpinx, he thought it was trifling in the face of grave dangers to risk their rupture by resorting to a useless and perhaps harmful treatment. After a surgeon had become sure of his diagnosis in these cases, as in cases of ectopic gestation, he thought the knife much safer and better practice. The great need of the times was a more perfect mode of diagnosis. He did not see why an error in diagnosis was any more culpable in pelvic than in abdominal or thoracic disease, but yet it was so regarded by many.

Obstetrical Society of Philadelphia.

Thursday, March 7, 1889.

THEOPHILUS PARVIN, M.D., IN THE CHAIR.

(Concluded from page 607.)

DR. MONTGOMERY: We have become so enthusiastic in the field in which we are working as perhaps to overlook the dangers and difficulties that environ the way, and in our desire to defend and possibly to push forward our own work we

are sometimes led not to report our disasters. I think that Dr. Baldy has done us a kindness in dwelling on some of the disasters that may occur in abdominal operations. I am rather surprised to find that hernia is such a frequent lesion, in his experience. I have not found it so. The method of closing the wound suggested by Dr. Price, is the one that I have largely used, and unless Dr. Baldy has come across some case of which I do not know, I have never had a hernia in my experience. Fistulas with a constant discharge are exceedingly depressing and distressing. I have thought that drainage per vagina might be preferable where this accident is liable to occur. In such a case, if fistula did follow, it would not be so bad as if it were in the abdomen. I operated this fall on a case in which half a gallon of broken down blood was removed from a sac. The sac was drained, but death occurred in a few days. The post mortem showed an abscess below the sac, which would have been opened if vaginal drainage had been made. The after treatment is exceedingly important in many cases. These results are, no doubt, due to the fact that there still remains some diseased tissue about the ligament or uterus. Where the tubal disease is gonorrhœal it is very hard to tie close enough to the uterus and to remove all the pyogenic membrane. Even when we do, the inflammatory condition is still present in the uterus. The tendency of the extension of such inflammation to the pelvic tissue is, in many cases, the cause of after trouble.

DR. HIRST: In three cases he had lately to deal with, fistulæ directly followed laparotomy. One woman died a year after the operation in consequence of this complication. In one case of great interest a mass of ligature was fished up, but the fistula still remains. After waiting sometime he opened the vault of the vagina, behind the uterus, on to a point of a sound passed into the fistula from above. He did not think he could have opened the bladder, but a vesical fistula must have already existed, for when he cut through the vault of the vagina urine gushed out. A drainage tube was put through the whole track, but now four months have passed and the woman is dying. He should hardly think the use of nitric acid free from danger, used as recommended by Dr. Goodell.

DR. HOFFMAN: The paper of Dr. Baldy is iconoclastic. He looks at the matter from the wrong side. He collects a number of bad cases, and puts them forward as an illustration of all abdominal surgery. If we look at his collection in the light of the fact that each case represents but a small proportion of the work of each man, the percentage of bad cases will be found to be almost infinitesimal. I, myself, do not believe that, in the light of the bad showing which Dr. Baldy has made, if we to-morrow met with a case

such as Dr. Price has referred to, he would hesitate one moment to operate. He would trust to doing his work well, and would feel sure that in nine cases out of ten he would have a good result. A report in a journal a few days ago shows that a prominent operator caused two deaths, because he did not know how to tie the ligature. If a man does not know how to tie a ligature, that is no reason why abdominal surgery should be condemned. In my own experience he had never had a fistula follow these operations, nor has he had a hernia. Early rising is wrong. I know of an operator who boasted that his patient had gotten up at the end of a week, rode home and walked up two flight of stairs to her room.

DR. BALDY: I did not bring these cases forward as an objection to abdominal surgery, nor would they, nor many more, stay my hand if I found a case which required operation. My desire was to call direct attention to such accidents as these, and to stimulate our efforts to prevent their frequency. Nor is this, by any means, a complete list of all the cases on which I could put my hands. I could add dozens to the ones I have named. These cases have occurred in the hands of prominent men, men who profess to be teachers, and who number their cases by the twenties, fifties and hundreds. If we see such accidents in the hands of such men, we shall have more serious results in the hands of those less expert. Many cases of fistula can be avoided by care in the use of the drainage tube. Few surgeons understand how to properly take care of a tube. I cannot agree with Dr. Price that fistulæ always follow old fistula tracks, and is caused by diseased tissue left behind. In the majority of cases that I have seen, the diseased tissue has all been removed, and the track occurs through what was formerly clean, healthy tissue. I think that one common cause of hernia is the use of hæmostatic forceps. These bruise the tissues, and if allowed to remain on too long cannot but irreparably damage the vitality of the parts included between the blades. The less we use the forceps the better union we will get. It is a rare occurrence that I have to use more than one or two pairs, sometimes three. These are always removed in a few moments, in fact as soon as I open the peritoneal cavity. They are no longer needed, and often, if you are working through a small incision, are in the way. The fewer foreign bodies in and about the abdomen and abdominal wound the better for the patient and the easier for yourself. Cleanliness in all its details cannot be too strongly insisted on.

DR. E. P. BENARDY reported the history of a case of

SUPPRESSION OF URINE FOR SEVEN DAYS IN A CHILD TWO YEARS OLD, WITHOUT SERIOUS RESULT.

I report this case on account of its rarity. The case seems to me to be one of idiopathic suppression of urine. No assignable cause could be found, the little patient had enjoyed good health up to the time of its illness; never had measles, scarlet fever; in fact, none of the diseases of children; had an attack of catarrhal pneumonia when eight months old. I was requested to see the little patient on the evening of August 17, 1888. He had been ailing for the past few days, disinclined to play, when well of a lively disposition. Nausea was present, and vomiting had occurred during the day; tendency to loose stools, tongue clean white and flabby; skin white, eyes dull, pulse quick, no fever; ordered pepsine mixture. The next day, stomach more irritable, could not retain anything, had an attack of hiccough, pulse full and quick, no fever; was informed by the mother that the child had not passed any urine since the evening of August 1, 1888; ordered xx gtt. spt. æther nit. in warm water every hour or two. The following day (August 19, 1888), condition about the same. Passed about quarter of teaspoonful of pure blood from the penis. Examination over region of bladder showed no indication of fluid. Ordered a warm digitalis and flaxseed poultice to be applied over region of kidneys; a bitart. potassa mixture, with infusion digitalis, internally. August 20. No improvement. Did not sleep well during the night, eyes dull, twitchy movements of the muscles of the upper and lower extremities, easily started. August 21. Twitching increased, face of waxy hue, skin hot and dry, bowels opened several times. August 22 and 23. Skin burning hot, restless, sleepless, twitching excessive, head thrown back, eyes dull and heavy, face puffed, skin waxy, lips bloodless, no pain locally, even when pressure is made. August 24. Close examination over region of bladder shows it empty; 6 dry cups over kidneys and other treatment continued. Five hours later, passed a large quantity of clear urine. August 25. All nervous symptoms abating, eyes clear, stomach less irritable, passed urine of a light-yellow color. Improvement continued and patient discharged September 5, 1888.

The first thing that impresses us is the few dangerous symptoms apparent in the case. We know when complete suppression or even partial suppression of urine takes place in kidney troubles, how soon the case terminates in coma, convulsions and death. Leaving out the suppression of urine in the above case, there was no possible symptoms indicating the dangerous condition of the patient.

The literature on this subject is meagre, the only work on practice which mentions the subject is the sixth edition of George B. Wood's, on p. 676. On suppression of urine, he states, "By suppression of urine, as a title of a distinct af-

fection, is here meant either a complete cessation of the secretory action of the kidneys or a diminution of it so considerably as to be clearly morbid. It is undoubtedly in general, perhaps always, a mere symptom or effect of some other disease; but instances occur in which no other affection is obvious; and in these it must in the present state of our knowledge be considered as idiopathic." On p. 677—"a rare form of suppression, occurring apparently as an idiopathic affection, was described by Sir Henry Hallford, and has been occasionally met with by other practitioners. A person in apparently full health observes that he passes little or no water, but suffers from no other inconvenience than a feeling of restlessness and anxiety, with perhaps a little uneasiness in the lumbar region. After a day or two he is seized with a chill, or finding the urinary affection unabated, becomes somewhat uneasy and applies for medical advice. There is no fulness or pain over the pubes or in any part of the abdomen, no febrile action, no symptoms whatever calculated to call attention decidedly to the kidneys, except simply that of great deficiency or absence of urine. No effort on the part of the patient is of any avail in increasing the discharge, and the introduction of the catheter is followed by the escape of only a few drachms of a pale, somewhat turbid urine, usually coagulated by heat and of little density. In a short time, however, nausea comes on, and increases until vomiting results; and this continues afterwards to be one of the most troublesome symptoms. The patient becomes dull and torpid; the pulse, so far from being excited, is usually less frequent than in health. The urine, if not completely suppressed from the beginning, now becomes so. A urinous odor is sometimes exhaled from the surfaces. The dulness increases to drowsiness, with occasional signs of mental wandering or incoherence. Eructations and hiccoughs are not infrequent symptoms. In about four or five days the patient sinks into coma and dies afterwards in the midst of repeated convulsions."

Many of the above symptoms were well marked in our little patient's case. Notably, the condition of the pulse, no febrile reaction, or little if any. An absence of any dangerous symptoms likely to attract attention.

DR. CHAS. B. NOBLE reported

A CASE IN WHICH FOUR DRACHMS OF SQUIBB'S
F. E. ERGOT WAS ADMINISTERED EARLY
IN LABOR.

On the 30th December last I was called to attend Mrs. M. in labor with her second child. Vaginal examination showed that labor was just beginning. The os was slightly patulous. The vertex was presenting, but the head was not deeply engaged in the pelvis. Abdominal pal-

pation showed that the child lay in the first position. Mrs. M. had had malarial intermittent fever during the preceding week, but had treated herself with quinine. This being her "child day" I ordered her ten grs. of quinine, and at the same time wrote for an ounce of f. e. ergot to be used after the completion of labor. On my return, after a short absence, I was informed it was well I had come. One should never be surprised in obstetrical practice, but as I hastened my steps I reflected upon how easy it is to be mistaken in prognosis. Upon reaching the head of the stairway I heard a groan, as if issuing from one in the final throes of labor. On entering the bedroom I was met by the statement, "Oh, doctor! your medicine is bringing it," and was told that violent pains had come on about an hour after my departure. Questioning the patient about the medicine, I was told that her mother had given her three spoonfuls of the ergot—the mother knew the odor of ergot, and had taken it in many of her ten labors. The bottle of ergot was half empty. The violent, and as I now found continuous, pains were thus explained. Telling the patient that her mother had anticipated my wishes in the administration of the ergot, also that no harm had been done,—which, however, I was not so sure of—I proceeded to examine into the condition present. The woman was suffering agonies, the uterus was rigidly contracted, and it not possible to demonstrate any rhythmical relaxation. Internal examination showed the cervix fairly dilatable, but the os was not larger than a half dollar. The foetal heart could be plainly heard, but was beating faster than at my first visit. Evidently the condition was somewhat serious. I administered a hypodermic injection of $\frac{1}{4}$ gr. morphia with atropia to the patient, and then gave chloroform freely enough to suspend the reflex abdominal contractions, which were well marked. From the combined effect of these remedies an improvement was soon noticed; the continuous, or nearly continuous, ergotic contractions were replaced by rhythmical contractions; the cervix dilated rapidly. When the cervix was pretty well dilated I ruptured the membrane to hasten the labor, as the foetal heart beats were not so easily heard as before, and as the case was at that time easily under control of the forceps. I felt much inclined to apply the forceps to expedite delivery, but concluded that it was best to watch the foetal heart and interfere on indication. Labor progressed rapidly, and in little over an hour from the time chloroform was given the head was on the perineum. There it was arrested by a cicatricial band, extending across the vagina, the result of a laceration during the first labor. As it was evident that this would not stretch, and as the foetal heart sounds, while still to be heard were less distinctly audible, I made traction on

this band with two fingers until it gave way. The child was born soon after, without further laceration of the pelvic floor. When born it was in a state of *asphyxia livida*, but cried and breathed nicely after a little blood was squeezed from the cut end of the cord, and the dorsum rubbed, the head in the meantime being held dependent. The child subsequently did well; having, however, a hoarseness of the cry, which has not disappeared. The mother also did well ultimately, although she suffered from fever for some days. This case was of exceeding interest to me, as I had never before witnessed the full physiological effect of ergot on the parturient uterus. At this time such cases are seldom seen, and it is on this account that I have reported this one to this society. I hope it may prove interesting, at least to the younger members; and perhaps elicit discussion as to the true place of ergot in the therapeutics of obstetrics.

DR. LONGAKER had only seen the action of ergot on the parturient effort, in the hands of midwives, and then always with disastrous results. The character of the pains was as described by the reader of the paper, and when given in any large quantity the child was always still-born. From the spasmodic condition of the uterus the delivery of the placenta had been difficult in several cases. In one case an anæsthetic was required. The midwives always use powdered ergot. The only place for ergot was after labor was completed.

DR. VOGLER had used ergot freely, particularly where there was inertia, where the pains are irregular, and in hysterical women where we can not get them to regulate the pains. He had not had any of the difficulties spoken of. It was a common habit of midwives to use it freely. When properly used, particularly after the first stage, it is safe and of value. He always used Squibbs' ergot.

DR. HOFFMAN would ask those gentlemen who were connected with large lying-in hospitals, whether or not they found it necessary to use ergot after delivery. In his own practice he did not use it at all, and believed that we could get along as well without it as with it.

DR. J. PRICE simply continued the use of ergot at the Preston Retreat, which Dr. Goodell had used before him. At the termination of the third stage of labor the patient received a drachm of ergot. If the third stage of labor is a complete one he hardly thought that ergot was needed. He had known it to produce nausea in sensitive, irritable women.

DR. HIRST followed the same practice as Dr. Price. There is one use of ergot he had learned in Berlin. In cases where post-partum hæmorrhage was feared, it is customary there to give a syringefull of ergot hypodermically when the head is delivered. By the time that labor is

completed the action of ergot will be manifested.

DR. J. PRICE said that in the cities we know nothing of the disastrous results of the abuse of ergot. He had recently seen, in a mining town in the State, some frightful mutilations of the soft parts. He saw there more in one day than he had ever seen in the city, of these bad tears. On inquiry he found that it was a common custom to use ergot in the first stages of labor.

DR. BALDY thought that medical men were often tempted to overdose their patients and that the use of ergot was a case in point. Early in his practice he had used ergot after the third stage simply because he had been so taught. He found his patients complaining severely of after-pains and so was led to stop it. He had not since then seen a case which required its use.

DR. NOBLE was in the habit of giving ergot after labor was completed. He continued its use for some little time afterwards, not to produce after-pains, as happened to Dr. Baldy, but to prevent them, and had often saved himself the inconvenience of a second visit by so doing.

DR. W. H. PARRISH reported cases of

COMPRESSION, WITH THE FORCEPS, OF THE CORD
WHEN IT IS AROUND THE NECK OF
THE CHILD.

He said he believed that this occurred oftener than was supposed. During the last few years, in cases of still-birth, where the cord was around the neck he had tried to ascertain if this had been the cause of death. In two instances he had established to his own and others satisfaction that this was the cause of death. In the first instance the patient had been delivered five times previously, with four still-born children. The child was not very large and the delivery was an easy one, without any especial compression with the forceps. He was surprised to find the child was dead and could not be resuscitated. As the head was about being delivered he removed the forceps and took the cord from around the neck. He afterwards replaced the cord and re-applied the forceps, when it could be seen where the tip of the blades had compressed the cord. In the second case the child was small and the pelvis roomy. The only cause of delay was inertia. The cord was again replaced around the neck and the forceps applied. It could then be seen where the cord had been compressed between one blade and the mastoid process. There are some forceps more likely to produce this compression than are others. Where the tips of the blades closely approximate each other, and where the blades are long, compression of the cord is more likely to be produced. This objection applies to such forceps as those of Wallace, Davis, Hodge, Tarnier, and similar instruments. Compression is less likely to occur with forceps like those of Simpson's, where the space between the tips is greater. Com-

pression of the cord would be more apt to occur if one blade was applied at any point behind the ear. It is also apparent that with a small head the cord will be more readily compressed, if about the neck. If the forceps are applied after the head is in the pelvis and flexion has taken place, and the long axis of the forceps coincides with the occipito-mental diameter of the head the cord is safe. In any other method of applying the forceps the cord is not safe. If the forceps are applied early in labor there is more chance of compressing the cord than if we wait until the head is in the pelvis. It will also be noticed that if the forceps be not applied to the sides of the head, even after flexion, there is danger of compressing the cord. How many deaths occur in this way we do not know, as the forceps are usually taken off and the cord removed from the neck before delivery; unless the cord is replaced and the forceps re-applied there will be nothing to indicate the true cause of death.

DR. G. E. SHOEMAKER reported a case of

TUBERCULAR PERITONITIS.

Woman, æt. 23. Complained chiefly of pressure symptoms from ascites. Probable diagnosis of tubercular peritonitis made before operation, which was undertaken for this condition. Nodules felt in peritoneum of recto-uterine pouch, by the rectum. Short incision; flushing with boiled water; glass drainage for two days. Prompt recovery from operation. Patient considers herself entirely well four months afterward, but some fluid has re-accumulated. As an aid in the difficult diagnosis the importance of rectal examination of the peritoneum was pointed out, though it may not separate papilloma and malignant disease of the peritoneum from tubercular. The writer has collected 35 genuine American cases, not all reported. Of these 6 died immediately after the operation, and probably in consequence of it; a mortality of 17 per cent., as against one of not quite 7 per cent. in 88 non-malignant cases of exploratory laparotomy selected from those collected by Dr. Baldy, as having no disease of the peritoneum. Kümmel reports 39 European cases, with two deaths from the operation (elsewhere quoted as 6); while Fehling has collected 29 cases, with 6 deaths, probably the same cases as those referred to by Kümmel, with a different interpretation of the deaths. Only 11 of the writer's 35 cases are known to have remained well more than six months. He refers to the varieties of the disease as influencing prognosis, and also to the theories as to cause of cures. He reaches several conclusions, among them, that the best treatment is laparotomy, with boiled water flushing and drainage. No medication of the cavity. Also that the most that can be looked for in more than one-half the cases is temporary improvement, but that this is usually decided and far outweighs the risk of incision.

DR. J. M. BALDY was rather surprised that the speaker should have come to the conclusion that exploratory incision in tubercular peritonitis was more fatal than in other forms of disease. Some time ago in examining the records he had found 17 cases, with but 1 death, and that in no way due to the operation. The double-pneumonia case mentioned might safely be excluded also. Without excluding just such cases, the mortality in exploratory laparotomy for any and all causes, had arisen to over 16 per cent. in a list of 154 cases he had collected more than a year ago. Certainly it is not fair to attribute such deaths to the operation. For instance, one case had died from a piece of gut getting into the incision and becoming gangrenous.

DR. SHOEMAKER: Dr. Baldy did not collect all the cases of death for America. If we analyze our cases too closely we should get statistics which would not be fair to the patient.

FOREIGN CORRESPONDENCE.

LETTER FROM VIENNA.

(FROM OUR REGULAR CORRESPONDENT.)

Nerve Stretching for Tabes Dorsalis—False Anurism Mistaken for an Abscess—Ichthyosis Partialis—Fortal Ascites an Obstacle to Delivery—Herpes Zoster Caused by Arsenic—Relations of Neuralgias and Psychoses—Death of Prof. Soyka, of Prague, etc.

At a recent meeting of the Vienna Medizinisches Doctoren Collegium, Prof. Moriz Benedikt, our distinguished neuro-pathologist, read a very interesting and important paper on the stretching of the nerves in tabes dorsalis. The lecturer first brought forward a patient, 40 years old, who had come under his care about three and a half years ago (on June 8, 1885). The patient, at that time, presented symptoms of tabes dorsalis to so high a degree as the lecturer had never before observed them. The patient could stand upright only when supported at both sides of her body; in this situation she could also take some steps, but her gait had a pattering (loitering) character to a high degree. The patient also presented symptoms of ataxia in sedentary position. When the patient sat in a dark room, with her eyes closed, she began to wave, and fell from her chair. During the night the chamber of the patient had to be lighted, otherwise she was cast out of her bed when she turned over in it. Her tendon and papillary reflexes were, of course, quite extinguished. Deep anæsthesia of the skin, the muscles, and all the surfaces of the joints of the legs; anæsthesia of the fingers; ataxia of the arms; frequent and severe attacks of lancinating pains in the whole body. The disease under consideration was present for at least four years.

The lecturer, taking into account that the usual methods of galvano- and hydro-therapy—which were efficacious in numerous other cases—offered but little chance of recovery in such advanced cases as the one referred to, determined on performing the stretching of the right crural and the left sciatic nerves. The operation, in such a case, was, indeed, rather an act of therapeutic despair, but the success obtained surpassed all expectations. On the eleventh day after the operation, the patient left the hospital, and was immediately able to walk alone. The ataxia in the lying and sedentary positions had disappeared, leaving behind almost no trace of the former conditions.

Setting aside the considerable improvement which had been produced by the extension of the nerves, the advantage of this treatment also consisted in the fact that the patient now became accessible to the treatment with the galvanic current. Though ataxia of a high degree had still remained behind in the legs, and was now present, the patient was soon able to undertake great excursions without availing herself of a stick. The attacks of pain were particularly frequent and severe the first year, but they gradually and constantly became more rare, and during the last fifteen months, no single attack of pain had occurred. The last-mentioned fact was so much the more to be considered as the result of the operation of the extension of the nerves, as we knew by experience that galvanization had but little influence on the tabetic neuralgias. Prof. Benedikt had the opportunity of observing such an effect of the stretching of the nerves also in other cases. The patient was able to perform the domestic work, such as washing and cooking. The anæsthesia of the legs persisted in only a little ameliorated condition, and this was also true of the ataxia of the arms. The patient, however, was sitting and standing upright with closed eyes, surprisingly well.

Prof. Benedikt made some interesting critical remarks on the extension of the nerves in tabes dorsalis, and said, among other things, that he knew from numerous neuro-chirurgical experiences that the success of the surgical interference depended mainly on the fact whether the disease was of a recent date or not. It was just in the case of ataxia that it was still now difficult to operate upon recent cases, as the respective patients, being influenced by the ever-predominating views, withdrew from the operation. It was the conviction of the lecturer that the percentage of successes would increase considerably if the operation of the stretching of the nerves in tabes dorsalis was performed immediately after the exact diagnosis had been ascertained. Prof. Benedikt declared it to be his full conviction that, perhaps in the next generation, the non-operating at the beginning of the ataxia would be considered as a professional error. In obsolete and much pro-

gressed cases the chance was naturally much less, but that there was some chance was proved by the case brought before the Society.

Disadvantages to the patient from this treatment could now-a-days be no longer feared. In the first period of these operations, the fatal issue was not rare, and the lecturer himself had, in former times, the opportunity of observing some such bad results. The operation, however, as it was now practiced by Prof. Benedikt, was scarcely more dangerous than the extraction of a tooth or the cutting of corns (*clavus*).

If the operator would guarantee for the good success of the operation, he had to conduct the after-treatment for a long time, and continue his respective observations. The present doctrine of the inefficacy of the extension of the nerves in *tabes dorsalis* was chiefly due to the too short period of observation. If a doctrine had to be classical, *i. e.*, true for all times, it ought not to be in a hurry.

Dr. Hochenegg, Assistant to Prof. Albert, at the first surgical clinic of Vienna, brought forward before a recent meeting of the Imperial Royal Medical Society, of Vienna, a case in which he had mistaken false aneurism of the left femoral artery for an abscess, and had opened it. Küster had recently reported on similar cases, and in surgical literature there were hitherto only five such cases on record. The man, shown to the Society, 41 years old, had sustained, in 1878, a shooting-lesion in the middle of the left thigh, and at that time, after seven weeks' treatment, was dismissed from the hospital as cured; the bullet of the fire-arm had not been detected. In 1886 the patient complained of temporary pains in the thigh, and the ankylosis of the knee-joint also gave him some annoyance. In April, 1888, the pains in the left thigh became more severe, and the patient, moreover, stated to have felt, at the inner side of the left thigh, a solid tumor, which could be moved over the bone, and which disappeared at a later date.

On October 18 of last year the patient was admitted into the clinic of Prof. Albert, and stated that he had been taken ill under severe attacks of shivering, which repeated from twice to thrice a day; the solid tumor, the size of a walnut, had again appeared. On the examination of the patient a fluctuating tumor of the size of a fist was detected upwards of the internal condyle; the swelling was very painful on pressure, and the skin over it was dark, reddened; the surrounding parts were œdematous. Dr. Hochenegg made the diagnosis of an abscess of the periosteum, as all the symptoms pointed to such a condition. When he made the incision on the following day, he became aware of a blue membrane, which became torn; loose bloody clots and arterial blood discharged at the same time. After having applied the band of Esmarch Dr. Hochenegg emptied the

cavity and detected: 1, the bullet; and 2, a large piece of bone which stuck in the artery. The artery was ligatured above and below the cavity; the further course was very favorable. Disturbance of circulation was present only during the first few days; it, however, soon disappeared.

The patient had stated that he had worked hard on the day when he fell ill the last time; it was thus probable that the bullet, which was hidden, had sunk in the course of these years, and had driven the loose piece of bone into the artery. The tumor had repeatedly been palpated for ascertaining the position of the arteries, but on no occasion could pulsation or vesicular murmur be found. All these occurrences explained the diagnostic error.

At a recent meeting of the Royal Society of Physicians of Budapesth, Dr. S. Róna showed a child, 15 months old, which was affected with *ichthyosis partialis*. He had observed the child for four months without noticing any change in the process during this period. The first eruption with red patches in the face occurred during the third month of life of the child. In the fifth month the skin over the back and the sacral region became reddened and squamous, and soon afterwards these changes also supervened on the extremities. The *ichthyosis* was to be met with very rarely at such an age; according to Hebra, the *ichthyotic* process did not set in until the second year of life, and even then it appeared only as *pytirisiasis*, or *ichthyosis simplex*. It was interesting to see how, in the case brought forward before the Society, the cutis had already begun to shrink to such a degree that *sclerodactylia* was already present on the hands and feet. It seemed that the nearer the beginning of the *ichthyosis* was to the foetal life, the more dangerous this dermatosis was. In the first child of the mother of the little patient, which was born two years ago, *ichthyosis universalis* occurred in the second year of age, owing to which the child was quasi-transformed into a mummy, and perished.

Dr. Hubert Peters, assistant to Prof. Gustavus Braun, recently reported, before the Vienna Obstetrico-Gynaecological Society, on a case of *ascitic dropsy* to a high degree, which formed an obstacle in parturition. The case was particularly interesting owing to the fact that the obstacles in delivery due to pathological enlargement of the infantile abdomen were exceedingly rare. The woman was admitted into the clinic as a *bipara*, and stated that the first birth was normal, and the foetus well nourished. According to the statements of the mother, the rupture of the foetal membranes supervened some hours before her admission into the hospital, when about four litres of amniotic liquid escaped. The abdomen, which was before excessively extended, thus diminished to only a little degree.

On the external examination the abdomen was

found to be still much extended, and the palpation revealed the presence of quite particular conditions. At the bottom of the uterus a large, hard and movable skull could be felt; over the entrance of the pelvis, apparently small buttocks were felt. In the whole body of the uterus (corpus uteri) there was uniform tension; the fluctuation was not distinct. The sounds of the heart of the fetus could be distinctly heard on the left side of the bottom of the uterus near the skull. The back of the fetus could nowhere be felt.

The internal examination showed the following conditions: The uterine orifice had the size of 5 centimetres; both the feet were to be felt there. In the course of some hours the feet, owing to slight labors, gradually advanced as far as the vulva, and it could be stated that the size of the feet stood in no normal proportion with the size of the skull and the abdomen felt on palpation. As there was no sure evidence of the presence of a twin fetus, and taking into account the frequent combination of hydramnion and monstrosity of the fetus, they thought in the clinic of such a combination. The extraction of the fetus was deferred for awhile, owing to the general weakness of the mother. On making the extraction the small buttocks were drawn as far as the entrance of the pelvis, when an absolute obstacle for further extraction proved to be present. The introduction of the whole hand of the operator into the lower part of the uterus revealed the fact that the obstacle was due to a colossal enlargement of the abdomen. As there was no possibility for making the extraction of the non-lessened abdomen, puncture of the abdomen was resorted to. In the absence of a sufficiently long trocar, Dr. Peters determined on performing perforation by means of the perforatorium of Nägele, which could be done with some difficulty. About $2\frac{1}{2}$ litres of a serous, cloudy fluid escaped, when the extraction could be performed without any inconvenience.

The child had died during the birth, and after the ascitic fluid had discharged it still weighed 4,000 grams; hence, in intra-uterine life it had the weight of 6,500 grams. The mother of the child left the hospital in perfect health.

At a recent meeting of the Royal Society of Physicians of Budapesth, Dr. Johann Bókai reported on a case of zoster, owing to arsenic. He showed a boy who had taken arsenic owing to chorea minor, and in whom herpes zoster pectoralis had developed on the twenty-eighth day after the use of the drug. Dr. Bókai had already observed similar cases, and particularly he had met with three such cases in 1883. Hutchinson, in 1868, had observed eight such cases. In the *Medical Times* of 1869, seven cases had been published in which herpes zoster had supervened after the use of arsenic taken for different reasons. Basing on these cases, Dr. Bókai considered the

herpes zoster, in the case under consideration, as being due to the use of arsenic, so much the more as the drug had, in this case, been administered for from twenty-eight to forty-five days, and the quantity of the solutio arsenicalis Fowleri taken amounted to from 257 to 450 drops. Except for slight conjunctivitis, no other symptoms of poisoning with arsenic were present.

Dr. Anton, Assistant to Hofrath Prof. Meynert, at the clinic for psychical diseases at Vienna, read a paper on the Relations of Neuralgias to Psychoses before the Imperial Royal Society of Physicians, of Vienna. He gave a detailed account of two cases of supra-orbital neuralgia in individuals who were affected with hereditary psycho-pathia, and in whom the neuralgia became associated with temporary attacks of loss of consciousness, and with complicated movements (biting, beating, stamping), and compulsory ideas of murder and suicide. There was, moreover, complete amnesia and permanent psychical depression; the whole complex of symptoms resembled very much that of epileptic mania.

As the bromide of potassium, antipyrin, anti-febrin, phenacetin, etc., proved inefficacious, faradization was resorted to with the best success. After the application of the electric douche with a gradually augmenting intensity, the neuralgic attacks completely disappeared; the relapses were easily combated, and both the patients were dismissed as cured, and had also become able to work.

The lecturer then discussed the relations of the neuralgias to the above-mentioned complicated movements, which he considered as being of a reflex character; and also their relations to psychoses, pointing out that with the removal of the peripheral irritation, the disturbances in the central organ could equally be removed.

Docens Dr. Eisenschütz directed the attention of the audience to an experiment which he had made in such cases. If he made an injection of morphine on a man who suffered from such neuralgias, the small and tense pulse became again soft and full, so that he could determine, by the palpation of the radial artery, the moment at which the injection had exerted its effect.

Dr. Anton confirmed the correctness of this observation, which he also tried to prove by the demonstration of the pulse-curves of the above-mentioned two patients before and after faradization; from the pulse-curve alone it became evident whether the patient was free of pains or whether he was suffering from pains.

Dr. Soyka, Professor of Hygiene at the Prague Medical Faculty, and a distinguished scholar in the domain of hygiene and bacteriology, recently died by suicide in Prague. This suicide was due to excessive nervous irritation. Soyka was descended from a psycho-pathic family.

Prof. Kahler, of Prague, the eminent neuropathologist, was intrusted with the second chair

for Internal Medicine at the Vienna Medical Faculty, which had become vacant by the death of Prof. v. Bamberger.

Vienna, March, 1889.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

New York Academy of Medicine—Section on Practice—Simulo in the Treatment of Epilepsy—The Significance of the Crepitant Rôle, etc.

At the last meeting of the Section on Practice of the Academy of Medicine, Dr. M. Allen Starr read a report of the new drug *simulo* in the treatment of epilepsy. Like others, his attention was first directed to the subject by the article of Dr. W. H. White, which appeared in *The Lancet* in March, 1888, and he gave a *résumé* of the observations of White and also those of Eulenberg, of Berlin, published in August, 1888.

White reported seven cases treated by this agent, all of them being cases in which renal fits occurred every week. In the first case neither *simulo* or bromide was of any particular benefit. In the other cases there was considerable improvement under the use of *simulo*, and in case number seven, which was one of unilateral spasms with paresis, the spasm was very much relieved by the drug, although it had not been affected by large doses of the bromides. He concluded his report by stating that he would not have it thought that *simulo* will cure epilepsy, but he believed that an improvement occurs under its use, and that it may be used as a substitute for the bromides when these produce ill effects.

Eulenberg reported that *simulo* appeared to have no effect whatever in cases of hysteria, and that in three out of four cases of epilepsy in which he employed it its effect was found to be weaker and less certain than moderate doses of the bromides (90 to 120 grains daily). In the fourth case, in which the use of the bromides for years had not succeeded in reducing the number of attacks below four to eight in a week, the effect of maximum doses of tincture of *simulo* (six drachms daily), was to reduce the number of attacks to two to five in a week. Subsequently he combined the bromides with *simulo*, giving a half dose of each, and the effect was at first as favorable as under the use of large doses of *simulo* alone. The frequency of the attacks gradually increased, however, and finally the patient was put back upon the bromides alone. Eulenberg's conclusion was that while *simulo* is not without use, it is decidedly inferior to the bromides in its effects.

Like White and Eulenberg, Dr. Starr used the tincture of *simulo*, in doses of from half a drachm to two drachms three times a day; and he gave

it in seven cases of extreme severity, which seemed to offer the conditions for a fair test of the powers of the drug. The first patient was a female 48 years of age, in whom the administration of the bromides was attended with very unpleasant effects. While the *simulo* appeared to prevent for a time the occurrence of an attack of grand mal, it had no effect whatever upon the numerous attacks of petit mal and hysteria from which the woman suffered. The second patient was a girl 12 years old, who had epilepsy from infancy, her attacks consisting of slight convulsions with loss of consciousness and loss of urine. The bromides had been used without any marked effect. Under the use of *simulo*, however, the attacks became reduced from about five a week to about three a week, while their severity diminished, and she no longer lost control of the bladder.

The third patient was a girl of 16, who had suffered from epilepsy, with both grand mal and petit mal attacks for two years. The *simulo* had no effect upon the petit mal attacks, but diminished the grand mal attacks from sixty-three in a month to four in a month. The month after this drug was discontinued, however, while taking bromide, chloral and belladonna the attacks of petit mal became very much reduced in number, and she had no grand mal attack whatever.

In the fourth, fifth and sixth cases *simulo* was given with apparently very fair results, although its administration was not kept up for any great length of time. The principal reason that Dr. Starr did not give the remedy a more extended trial was the costliness of the tincture of *simulo*, the price of which, he said, was 25 cents an ounce; and this constituted a serious objection in dispensary practice.

The seventh and last patient was a young man of 19, who had had precursive epilepsy since the age of seven; the attacks consisting of a sudden pallor followed by a flushing of the face and a sudden uncontrollable movement of the body. These attacks had never been controlled by bromides, and during the year 1888 they averaged one hundred a month. Under the use of nitroglycerine combined with bromides they were reduced one-half, but *simulo* had no effect upon them. In addition this patient had nocturnal convulsions, and upon these attacks of grand mal the *simulo* was found to have a decided effect, although this was pronounced as that produced by bromides.

The conclusions drawn by Dr. Starr from these cases are as follows:

1. Tincture of *simulo* has no effect upon attacks of hysteria-epilepsy, or upon the hysterical state.
2. It has no effect in modifying the frequency or severity of attacks of petit mal or of precursive epilepsy.

3. It has some effect in modifying the frequency and severity of attacks of grand mal, but is inferior in this respect to the bromides.

4. In cases where, for any reason, it is deemed necessary to suspend the bromides, it would be well to substitute simulo for them.

He then went on to say that there seemed to be no ill effects from the use of the drug. He found no evidence of change in the rate or character of the pulse or respiration, or other physiological effects, produced by the doses employed, and he thought it would be well to increase the dose progressively until 1, or even 2 ozs. were used daily. The suggestion of Eulenberg that the active principle of the drug should be obtained and employed he thought worthy of consideration.

The only one present at the meeting who appeared to have given simulo a trial was Dr. Landon Carter Gray, and he asserted that he had found it practically useless. He said he had employed it both alone and in combination, and he had obtained from it no results except such as one could get in almost any case of epilepsy by changing the drugs given. This was merely a temporary effect, and the same might be obtained by a hundred other agents. He had, therefore, discontinued the use of simulo, as it had in his hands proved so nearly useless that he did not feel sufficiently encouraged to pursue his investigations concerning it any further.

On the same evening Dr. F. W. Johnson read a paper on "The Significance of the Crepitant Râle," and the following are the conclusions to which his study of this subject has led him:

1. The crepitant râle is not pathognomonic of pneumonia.

2. It is heard also in dry pleurisy, in bronchopneumonia, and in phthisis.

3. There is a strong probability that it is almost always due to pleuritic inflammation.

4. The question as to whether it is heard also in œdema of the lungs and pulmonary apoplexy is unsettled.

As regards the mechanism of the crepitant râle the three leading theories are:

1. That of Laennec, according to which it is due to the bursting of fine bubbles of air through a viscid fluid in the air vesicles.

2. That favored by Walsh, that the sound is due to forcible distension of the air vesicles, whose walls are rendered stiff by a glutinous exudation.

3. That advocated by Dr. James R. Leaming, that it is produced by the rubbing together of the two surfaces of an inflamed pleura which is coated with fibrin.

All the older writers and most of the modern ones, said Dr. Jackson, favor the intrapulmonary origin of the râle; while many of the more recent writers and teachers, in New York at least, ascribe it to pleuritic exudation. Nearly all modern writers agree, however, in the opinion that it is not

pathognomonic of pneumonia. He then proceeded to give a *résumé* of a number of authorities, including Guttman, Eichorst and Jurgensen in Germany, Germain Sée in France, Reynolds, Samson Gemmell, W. Douglas Powell and Sir Andrew Clark in England, and Flint, Leaming, Loomis, Delafield and others in this country. He mentioned that Sir Andrew Clark, in his lectures on "Some Points in the Clinical History of Primitive Dry Pleuritis," distinctly referred the fine râles which he heard to changes in the pleura, and not in the lungs, and verified his statements with autopsies.

Dr. Jackson quoted at some length from Dr. James R. Leaming, of this city, who, as is well known, has for a number of years taught the doctrine of the interpleural origin of râles, which, although at first received with a storm of opposition, has at length been accepted, in part at least, by a considerable number of the profession. According to Dr. Leaming, the crepitant râle, although having its mechanism within the pleural cavity, is a valuable sign of pneumonia and of phthisis, though not pathognomonic, while it may exist in the absence of both, and either may be present without it. Dr. Alfred L. Loomis, Dr. Jackson said, regards the crepitant râles heard at the end of inspiration in the first stage of pneumonia as usually due to pleuritic crepitation, and considers the râle of pulmonary œdema as subcrepitant in character. Dr. Francis Delafield taught that the crepitant râle is heard in pneumonia, in phthisis, and in dry pleurisy, and that it is probably a friction sound. Also that the stage of congestion in pneumonia may give a subcrepitant râle and a crepitant râle if there be pleurisy early, and that the crepitant râle may persist in the stage of complete hepatization if the lung was enough.

Among the writers cited was Dr. J. West Roosevelt, assistant pathologist to the Roosevelt Hospital. In Wood's Handbook of the Medical Sciences he attributes the crepitant râle to the three possible sources before mentioned, but regards the rubbing together of the inflamed pleural surfaces as the most common; if, indeed, it be not really the only cause. Dr. Jackson went on to say that the exact study of the phenomena of râles demands that the sound shall have been heard at the shortest possible period before death, its position on the chest wall and acoustic characters carefully noted, and then that the lungs and pleurae be subjected to a critical post-mortem examination with reference to these data. In the cases which he has studied in this way he has found that when a fine râle was heard, on inspiration some pleural changes were commonly noted at or near the site of the râle, but not always of such a character as to be convincing. In an extended clinical experience, a point of view from which he said he could speak with more confi-

dence, he has noted some differences from the rules laid down in the text-books. Thus, he finds that the crepitant râle is not always persistent (sometimes disappearing and reappearing alternately in a short space of time), and the extremely fine, extremely dry sound occurring in a great number of crackles is a rare form of crepitant râle, whether associated with pneumonia or any other pathological condition. Of the brilliant, explosive, abundantly crackling type of râle, that which is slightly moist and a trifle more coarse in quality has seemed to him to be far more common, and he has frequently observed it in acute lobar pneumonia, acute dry pleurisy and phthisis, and less frequently in broncho-pneumonia.

Furthermore, Dr. Jackson has been struck with the number of patients who apply for treatment whose chief or only complaint is of pain in the chest and in whom careful examination reveals as physical signs a little dulness and a variable number of fine râles, either crepitant or sub-crepitant in character. These sounds are superficial, localized in a small area, and increased by cough or deep inspiration, and so common has he found this condition, which he regards as due either to old or recent fibrin on the pleura, or to pleuritic adhesions, that he rarely makes the diagnosis of intercostal neuralgia or muscular rheumatism. While it might be urged, he said, that these sounds are not crepitant râles, they corresponded in everything but the element of a "shower of crackles" to the definition, and they certainly constituted a very fine râle heard on inspiration. He has sometimes heard the crepitant râle persist during the second stage of pneumonia, though the number of crackles was much less than in the first stage, and in some instances it required strained attention to hear it. In conclusion, he stated that he had always regarded the râle of œdema of the lung as a subcrepitant râle of peculiarly liquid character.

In the discussion which followed the paper Dr. Roosevelt said that he had been correctly quoted by Dr. Jackson, but since the publication of the article referred to he had seen reason to modify his views to some extent. It was a matter of some importance, he thought, to understand just what was meant by a crepitant râle. If Leonard's definition was to be accepted, that it consists of a series of sharp, crackling sounds heard at the end of respiration, and apparently near the ear, it had to be admitted that the crepitant râle is met with in phthisis, in severe bronchitis, in pneumonia, in dry pleurisy, and in œdema of the lungs. As to the cause of the production of this râle, he did not feel prepared to express any opinion.

There could be no doubt he said, that there was a distinct movement of air in the vesicles. In pneumonia we talked of the solidified lung as not moving at all; but either the lung did move or else the pleura was immovable. A solidified

lung could be expanded to some extent, since the smaller bronchi occupied a considerable space. He would be inclined to deny, therefore, that the crepitant râle cannot be produced in the air vesicles. There could be no doubt, however, that the râle was also heard in pleurisy; and hence it was necessary to depend on other signs to differentiate between pleurisy and pneumonia. As to Dr. Leaming's teachings, he thought it was a great pity that so much of what was of positive value should be mixed up with that which was not proven. Frequently in the dead-house he had found the pleura perfectly healthy in cases in which a few hours before the crepitant râle was distinctly heard. Yet, at the same time, he believed that he was perfectly right in attributing the greater number of crepitant râles to the pleura.

Object of State Regulation of Practice.

Dear Sir:—It is doubtful if all other combined opposition to medical legislation has, or still exerts, effects equally fatal to its success, as the one false and mistaken idea that it is chiefly in the interest of the profession itself. It has been the great argument of every nostrum nabob and medical fraud, which the promoters of medical legal reform have been compelled to confront. But when the friends and advocates of such reform in the profession, so far misinterpret its true animus, purpose and operation, as to indorse this fatal error, one is scarcely able to repress an indignant protest.

A medical society at Green Bay, Wis., in a recent report of its action, saw fit to rise from its average to aid in lifting a medical act through the General Assembly of that State the following: "Whereas, for the better protection of the medical profession," etc. Permitting the phrase, Mr. Editor, what more complete "give away" could have been perpetrated—not to say fatuous proceeding—by intelligent gentlemen, than this is? When this legislation, of which that of Wisconsin is a duplicate, is in operation, all are aware that its benefits incur to the public, as no law can be obtained whose terms do not, in a degree, brace up existing incompetent practitioners to those of the qualified profession. It must be a present sacrifice to secure a future reward. No greater success can be warranted by reason, than our ability to bar the entrance of the public sheep fold against the wolves of the quack kingdom. Those already within cannot be expelled, but must be tolerated until the elimination of time completes their removal. Attempts to cleanse the body politic from all evil of this kind, and at one stroke, has been the cause of the array of mis-carriages lining the past course of medical legal history.

Yours respectfully,

Independence, Ia.

H. C. MARKHAM, M.D.

MISCELLANY.

ON VACCINATION.—*The Bristol Medico-Chirurgical Journal*, England (March, 1889), reviewing some books on Vaccination, says: "Vaccination has got into undeserved discredit by the way in which its details have been carried out by thoughtless or careless operators. It is much to be desired that all vaccinations should be taken out of the hands of private practitioners, and allowed to be performed only by public vaccinators. The difficulties in the way of this much-needed reform could be easily overcome. Vaccination, as an important branch of preventive medicine, should be under Government inspection. Not only is there great difficulty, privately, in obtaining trustworthy lymph, often necessitating a resort to unauthorized sources, but, in deference to the sentimental objections of ill-informed parents, there are many practitioners of good social standing who are not ashamed, by vaccinating by one or two small insertions, to earn a cheap popularity, although thereby a serious danger is added to the life of a child thus made unfit to successfully resist a possible attack of small-pox. There are also doctors of a lower grade who set themselves up in opposition to the public vaccinator, and, by performing the operation for a degrading fee of sixpence or a shilling, with a vaccination also much reduced in quantity—and therefore in quality—draw off a considerable number of ignorant mothers from the Vaccination Station, the efficiency of which becomes impaired through a greatly diminished attendance seriously limiting the selection of lymph, and the proper management of which becomes wellnigh impossible.

"In the light of Marston's figures (Seaton's Handbook of Vaccination, ed. 1868, p. 216; McVail, p. 36; Woodward, p. 15), confirmed by all after-experience, conduct such as this, in various walks of professional life, seems little short of criminal, and has now reached such appalling magnitude as to urgently call for Government interference.

"If vaccination is to be a reality, and not merely something which leads its subjects into a fools' paradise, the State must ensure, by an inspection through properly qualified officials, that it is carried out in all ranks of society in a thoroughly efficient manner."

DR. THOMAS LINN, an American physician who has resided for many years in Paris, has changed his residence to No. 161 Rue de la Paix. Dr. Linn is well known as the Paris correspondent of the *Philadelphia Medical Times*.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from April 20, 1889, to April 26, 1889.

By direction of the Secretary of War, the retirement from active service this date, by operation of law, of Col. David L. Magruder, Surgeon, under the provisions of the Act of Congress approved June 30, 1882, is announced. Par. 4, S. O. 94, A. G. O., April 23, 1889.

PROMOTIONS.

Col. Edward P. Vollum, Surgeon U. S. Army, promoted to Surgeon U. S. A. with rank of Colonel, from April 23, 1889.

Lt.-Col. Joseph P. Wright, Surgeon U. S. Army, promoted to Surgeon U. S. Army with rank of Lieut. Colonel, from April 23, 1889.

Major Ezra Woodruff, Surgeon U. S. Army, promoted to Surgeon with rank of Major, from April 23, 1889.

Lt.-Col. A. K. Smith, Surgeon U. S. Army, reports address of new Army Building, as at No. 39 Whitehall St., New York City. April 18, 1889.

Pursuant to instructions contained in letter from A. G. O., Washington, April 13, the following named medical officers will assemble with troops in New York Harbor on the 27th inst., prepared for field service in connection with New York Centennial parade: Major Robert H. White, Surgeon U. S. Army; Capt. Clarence Ewen, Asst. Surgeon U. S. Army; Capt. Jno. J. Cochran, Asst. Surgeon U. S. Army; and First Lieut. Chas. B. Ewing, Asst. Surgeon U. S. Army. S. O. 90, Hdqrs. Div. of the Atlantic, Governor's Island, New York City, April 19, 1889.

By direction of the Secretary of War, Capt. Ezra Woodruff, Asst. Surgeon, is relieved from duty at Ft. Missoula, Mont., and will report in person to the commanding officer, Ft. Monroe, Va., for temporary duty at that post. Par. 14, S. O. 72, A. G. O., April 20, 1889.

First Lieut. Freeman N. Walker, Asst. Surgeon, is granted leave of absence for four months on surgeon's certificate of disability, with permission to leave the Dept. of Texas, by direction of the Secretary of War. Par. 12, S. O. 92, A. G. O., April 20, 1889.

Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending April 27, 1889.

Asst. Surgeon Geo. B. Wilson, detached from the Naval Hospital, Mare Island, and to the "Iroquois."

P. A. Surgeon F. J. B. Cordeiro, detached from the "Vandalia," and to the Naval Hospital, Mare Island, Cal.

Surgeon John F. Bransford, ordered to the "Iroquois."

Asst. Surgeon Edward R. Stitt, ordered to the Bureau of Medicine and Surgery, Washington, D. C.

Surgeon N. M. Perebee, ordered to Naval Academy, Annapolis, Md., for examination of candidates for admission to the Academy.

ADDRESS.

LICENSE TO PRACTICE.

An Address delivered to the Medico-Chirological Faculty of Maryland.

BY WILLIAM OSLER, M.D.,

PROFESSOR OF MEDICINE, JOHNS HOPKINS UNIVERSITY, BALTIMORE.

Mr. President and Gentlemen:—I shall not offer any apology for making the "License to Practice" the subject of my address, as it is one in which all, high and low, rich and poor, lay and professional, are deeply interested. I am fully aware that it is a subject thought to require the delicate handling which we are accustomed to give to topics arousing heated discussion, and upon which diametrically opposite views are held. Still as the question agitating the profession to-day, it requires to be persistently and thoroughly ventilated, and those who have opinions on the subject should speak out in no uncertain tones. I have not had an opportunity of ascertaining the feelings of the members of the ancient and honorable Faculty on the question, one which touches closely I believe, certain vested right of this body; but I have learned that three years ago a Bill for a State Board was rejected, so I presume the matter has often been before you. I am the more emboldened, therefore, to speak freely, knowing full well that I address men who have given time and thought to the problem, who know its difficulties, and who appreciate its importance.

In this country, a man can follow the vocation he pleases, subject only to such restrictions as may be necessary for the public welfare. The right to regulate the practice of medicine rests with the State, and, I believe it is acknowledged that this right comes within that general police power which extends protection to the life and limb of the citizens. At present, this power is very variously exercised in different States. In many, no regulations whatever exist. Any one who wishes, irrespective of qualifications, can practice. In a majority, however, there are restrictions which demand evidence on the part of the practitioner that he has studied, for a longer or a shorter period, at an incorporated school. Practically, the rule prevails that with a diploma from a chartered school, he can begin at once,

without any hindrance other than that relating to registration. The educational duties of the State do not here extend beyond the system of common and normal schools, though, in a few, higher university work is also undertaken. Special education does not receive support from the public revenues. Schools of law, medicine, engineering, theology, all the special branches of study are, private enterprises, chartered by the State and maintained by fees from pupils, or by the munificence of private friends. Certain privileges are granted to these Institutions by the State, the most important of which, in the medical school, is the recognition of the diploma as a qualification for practice. So unsatisfactory, however, has this system proved, that there is on the part of the public, and of the profession, a growing sense of the necessity for radical changes as shown by the number of States in which bills have either been already passed, or have been before the legislatures dealing with the problem.

It is universally conceded that the basis of legislation is the necessity of protecting the people against the depredations of ignorant graduates and of quacks. The aim is to divide a minimum standard of qualification to be exacted of all persons who desire to follow the calling of physician and surgeon.

While we find legislatures everywhere willing to support enactments necessary for the safety of the public, they will not, (and it is right that they should not) support class legislation; and herein lies one of the chief difficulties.

If we look around upon those engaged in the practice of medicine, we find that an overwhelming proportion belongs to the regular, or so-called old school. A second small division professes to follow the precepts of Hahnemann; while a third, still smaller, neither one thing nor the other, but a little of both, professes a judicious eclecticism. These three bodies have schools, medical journals, and in each State a more or less complete organization. In the eyes of the law (which rightly disregards medical theories), all are equal. This unhappy division of the body medical is not limited to professional matters, but is complicated with ethical questions of the highest moment. The outcome of it all has been that there are hostile camps and bitter war.

The homœopathists, and the eclectics will, I think, concur in the necessity of a full and proper curriculum of study in the great branches of medicine. Anatomy, physiology, chemistry, histology, embryology, medicine, surgery, obstetrics, gynæcology, and medical jurisprudence know no "isms." The differences only become glaring when we touch the subject of therapeutics, a subject in which among members of each of the so-called schools the greatest individual differences of opinion exist. So strong, however, is the feeling (largely an ethical one), that the divergence of opinion on this one branch separates absolutely the different classes of practitioners from each other; nor do not say that this should not be so, while antiquated dogmas are professed in opposition to a rational and a free science.

We cannot, however, escape from the important fact that in the eyes of the law we all stand equal, and if we wish legislation for the protection of the public, we have got to ask for it together, not singly. I know that this is gall and wormwood to many; at the bitterness of it the gorge rises; but it is a question which has to be met fairly and squarely. When we think of the nine or ten subjects which we have in common, we may surely, in the interest of the public, bury animosities and agree to differ on the question of therapeutics.

In connection with the licence to practice, there are, it seems to me, three courses open: 1. A continuance in the plan at present, widely prevailing, which makes the college the judge of the fitness of the candidate; and State supervision is only so far exercised that the diplomas are *vised*, and registered, if from legally incorporated schools. 2. The appointment by the State or by parties so deputed of a board of examiners which shall, irrespective of diplomas examine all candidates for the license. 3. The organization of the entire profession in each State into an electorate which shall send representatives to a central parliament, having full control of all questions relating to medical education, examination and registration.

These various places are at present in operation in different parts of the Continent; let us see how they work.

And first of the colleges which have practically had a monopoly for years, as the diploma has carried with it the privilege of registration.

To all intents and purposes the medical schools of the country are private organizations, managed in the interest of the professors, who, with scarcely an exception, have direct pecuniary interests in the size of the classes. The greater number of students and graduates, the larger the fees, and the higher the income of the teachers. The running expenses and the interest on the moneys expended for the teaching-plan are the first call, after which the balance is divided. These chartered

corporations, are wholly irresponsible, without supervision by the State, the profession or the public. It would not be difficult, without fear of just rebuke, to bring a railing accusation against them for persistently acting in their own, and not in the interests of the public. But the time has passed for this. Yet, it is surprising to think that so many men, distinguished in every way in their profession, cultured and liberal, still cling to, and even advocate, the advantages of an irresponsibility, which has made the American *system* of medical education a byword among the nations.

Let me not be misunderstood. These very men are, in many instances, those whom we delight to honor, with names which will last as long as American medicine. Yet, to an unbiased mind, there can be no hesitation in affirming that the system which has been permitted to develop in our midst has done, nay, is doing, irreparable wrong. But, it may be urged, on the part of the schools, that they are what the profession wishes. The stream does not rise higher than its source. I do not think that this holds good at present. It does not require a very wide professional acquaintance to gather, that there is now developing, throughout the length and breadth of the land, an earnest desire to support a higher medical education, and this is borne out by the success which has attended the tentative efforts in this direction of the larger schools, which have made a three years' college course compulsory.

Here, let me remind those doctors who talk fondly of medical reform, of the selfishness of schoolmen, of the difficulty in getting colleges to advance, that very much rests with the degree of support given by them to those schools which really make sacrifices for the elevation of the standard. If, for instance, the University of Pennsylvania or Harvard, or the College of Physicians and Surgeons in New York, or the University of Maryland, were to extend to four full years the course of study, there would be at each of these schools, without the slightest doubt, a falling off in income from the reduction in the number of students. So much so, that it would be impossible to run these larger establishments at their present full equipment. Manifestly, it would be suicidal, without the guarantee of outside aid, to imperil corporate interests of such magnitude. But, if on the other hand, those physicians throughout the country, who strongly favor a four years' course as the minimum in which a man can obtain a reasonable knowledge of the science and art of medicine, if these men were to direct their students to such institutions, (and in this matter we all know how much influence the physician has), the problem would be at once solved.

Too often college faculties seem stricken with timidity in the presence of suggestions to lengthen the curriculum and to raise the standard.

Yet, a superficial study of the history of the movement since 1871 and 1872, when Harvard so nobly took the lead, should be convincing to all that even from the lowest considerations the advance should be successful. You have but to look to the condition of the schools which have been in the van, to see that the bread cast upon the waters has already been found. I do not say that these schools are in all instances the most prosperous numerically. Heaven forbid; that is not a standard of merit. But, take the laboratory equipment, the measure in which they fulfill medical requirements, the practical teaching and the development of clinical instruction, and I say without fear of contradiction, that these schools have met with an ample and a just reward. And yet, these are the very schools which clamor loudest for further advance, showing how dangerous it is to arouse the slumbering conscience and to abandon the conviction that a two session course is sufficient for the average American student. But in spite of all that has been done, in spite of the agitation which has been so active during the past ten years, the sad truth must be told that a large percentage of doctors are graduated annually after only two sessions of study.

On paper, the two session schools almost universally demand three years; one of which, it is stated, may be with a physician. Now, it is notorious in these schools that a large majority of the men receive the degree at the end of the second college year, and it is just as notorious that not 5 per cent. of the cases in which a preliminary year of study has been passed with a physician is a *bona-fide* period of medical instruction. It practically amounts to this, that a man enters without any fair preliminary test as to elementary education, say on the first of October of the present year, and eighteen months from date, or rather seventeen months, sometime in March, 1891, he will be let loose upon the commonwealth. Eighteen months in which to master one of the highest, as it certainly is one of the most difficult of the professions which man is called upon to practice! That, gentlemen, these are facts, sad facts, each one of you knows. Yet so blind do men seem in this matter, so wedded to this pernicious system, that I have known physicians in large practice, able, cultivated men, contributors to medical literature, standing high in the esteem of their brethren, permit their sons to follow out the curriculum. Picture if you can the mental condition of such a graduate; an incoherent jumble of theories, a chaotic assortment of what he would call practical tips. But this question has its tragic side, which completely overshadows everything else. It makes one's blood boil to think that there are sent out year by year scores of men called doctors, who have never attended a case of labor, and who are ut-

terly ignorant of the ordinary every day diseases which they may be called upon to treat, men who may never have seen the inside of a hospital ward, and who would not know Scarpa's space from the sole of the foot. Yet, gentlemen, this is the disgraceful condition which some school men have the audacity to ask you to perpetuate; to continue to intrust interests so sacred to hands so unworthy. Is it to be wondered, considering this shocking laxity, that there is a wide-spread distrust in the public of professional education, and that quacks, charlatans and impostors possess the land?

But the handwriting is on the wall, the interpretation has been read, and the prophesy indeed is in course of fulfillment. It needs not the vision of a son of Beor to advertise that within ten years in scarcely a State of the Union will the degree carry with it the privilege of registration; and with this removal of the kingdom from the schools will dawn a new era for the profession in this country. This will happen when unrestricted competition between the colleges, and the total absence of professional and State restraint are things of the past.

Under the second plan the entire question of registration is placed in the hands of examiners, appointed by the Governor or by the State societies. Such a board to be effective must constitute the only portal to practice. The practical working, as shown in North Carolina, Virginia and Minnesota, presents no difficulty, and it constitutes an effective barrier against the inroads of poorly qualified graduates. Within a few years this measure will be widely adopted. It has certain advantages in a simple mechanism, and in clearly defined duties. But the powers are too limited, and there is no control of education preliminary and special, such as comes strictly within the power of the profession in each State.

The record of the Virginia Examining Board for the four years ending October, 1888, is an excellent illustration of the good which may be done. Of 240 candidates examined 54, or 22 per cent., were rejected, a percentage which might be increased considerably if practical examinations were instituted in the practical branches.

Ultimately I believe a more elaborate plan will prevail more difficult to organize, but practical and possessing the great advantage of giving the control of the profession into the hands of the practitioners, and of doing away forever with the minority rule of the college.

Theoretically, there can be no question (particularly in democratic communities) that a State board should be elective, not appointed by the Governor or the societies. An elective board is in reality a medical parliament, which should take cognizance of all matters relating to medical education, and, perhaps, though of this I am not so sure, of questions of public health within the

State. The assembly districts or other territorial divisions which might be made, would send one, or perhaps two, representatives to the board (depending upon the professional population in each district). The electors would be constituted by all practitioners irrespective of schools, which had registered at a certain date. A man who had practiced, even without a diploma, for a certain time would, under these circumstances, have to be recognized and permitted to register.

The Governor of the State would issue the first warrant for the election, which would subsequently be the prerogative of the executive of the board. It might be necessary, at first, to have, from each district, members returned from at least three of the divisions which at present constitute practitioners. The representation should be per capita, the number of constituents in each electorate to be previously arranged. The term of the board should be, at least, four or five years, and members should be eligible for reelection. Conducted by ballot there should not be the slightest difficulty in carrying out such an election. There would be, of course, active canvassing, and perhaps, many nominated from one district. Though there would be opportunities for political trickery and gerrymandering, I think, on the whole, it would be found that an election could be conducted with tolerable purity. The universities and schools would have full representation on the board. To such an organization, I believe, might be intrusted the control of all matters relating to medical education in the State. It would correspond to the law societies, and to the synods and conferences of the various religious denominations. The powers of such a board would be accurately defined by legislation, and should relate first to preliminary education; secondly, to the examination and registration of candidates for the license to practice; and thirdly, the control of all matters relating to discipline with the profession. The necessary expense would be met—first, by the fees paid by the candidates for examination; secondly, by a small annual tax levied upon all registered practitioners. Such a body could look forward hopefully to a permanent establishment in each State, with buildings suitably equipped for examination, and with every possible provision for conducting, in an orderly and systematic manner, the business of the profession.

The first important function of the board would be the regulation of the minimum standard of education required in entering the profession. It is perfectly legitimate that the profession should say, through its representatives, what should be the qualifications of a candidate who desires to enter upon the study of medicine. In law this holds good; why should it not be so with us. A guarantee of uniformity would thus be given which cannot be expected in the schools.

The examiners at the preliminary test should be independent teachers, not professional men, and the examinations could be arranged in different parts of the State. The period of study would date from the passing of this preliminary examination. Such a measure would effectually prevent the entrance of men whose education was such that they could not subsequently grapple with the subjects of professional study.

The examination and registration of candidates would constitute the most important function of the board.

Upon no question will there be a greater diversity of opinion than upon the selection of examiners. The opposition to State Boards on the part of school men is very largely based on the doubt which they have as to the selection of thoroughly equipped men for this work. On the part of the profession such a feeling exists that would prevent the appointment by the board as examiner on his own subject a teacher in any school. The difficulties, however, are not insuperable. With the proper system of numbers for written examinations, and with two examiners at every oral, there could not be the slightest objection, so far as I can see, to the selection of school men as examiners in certain of the branches. In anatomy, chemistry, physiology and pathology, that is to say in all the scientific branches, it would be almost impossible to secure from the general profession examiners with the necessary training. It certainly would be most unjust to well-equipped students from the laboratories of our first-class schools to subject them to examinations on these branches by men who had crammed on purpose from two or three of the most recent text books. On the other hand, in the more practical subjects, there are certainly in each State to be found men fully capable of conducting the necessary test work. I have the honor to know personally, in many States of the Union, men to whom I would intrust with the utmost confidence, the examination of my students in the theory and practice of medicine, and I doubt not that in surgery, midwifery, gynecology, and in the polyglot subject of therapeutics men equally able in these departments would be forthcoming.

There need not be any difficulty in the existing differences between the various schools of practice. All students would be examined in the great primary divisions, anatomy, physiology and chemistry, and so also in pathology and morbid anatomy, in obstetrics and in operative gynecology and in medical jurisprudence.

The examinations in these branches would be uniform. In therapeutics only would there be separate tests for regulars, homeopathists and eclectics. On application, the student would have to indicate for which of the three he wished to apply, and, if successful, would be placed in

one of the three divisions of the State Register. I am free to confess that this scheme may, to some, seem Utopian, but I am firmly convinced that the majority of those who hear me to-day will live to see State Boards organized on this, or upon a modified plan.

With the third function of the Board, viz., that relating to discipline, I need not detain you further than to say that in any effective act there should be penal clauses giving authority to prosecute irregular and unlicensed practitioners; to remove for cause a name from the register; and to exercise such additional powers as might, in the opinion of the framers of the bill, be thought justifiable.

Now the entire feasibility of such a scheme is illustrated by the professional history of the Province of Ontario. Up to 1865-6 a Licensing Board appointed by the State which dealt, however, in examinations only in the case of candidates without diplomas, but to all intents and purposes it was simply a Board of Registration to which holders of degrees presented themselves, paid a small fee and obtained the license. The schools practically controlled it.

In the session of 1865-6 the profession of the Province sought incorporation, and the Act was framed which, with certain important modifications, at present remains in force. It practically hands over to the profession, through the elected representatives, the management of their own affairs so far as they relate to preliminary and professional examinations and certain disciplinary enactments. In spite of the strenuous opposition on the part of many who felt that it was a most degrading thing thus to lop the important privilege hitherto held by the Universities which enabled graduates to obtain the license without further examination. In spite of dissensions and dissatisfaction, such as are almost inevitable in connection with a new organization, the Board has persisted in its good work and to-day, after 23 years of existence, it has a record of which the entire profession of the Province is most justly proud. On no point was opposition more bitter or more prolonged than on the admission to representation of members of the homeopathic and eclectic bodies. My very first introduction to the profession was a visit with my preceptor to the committee room of the House, in which certain amendments to the Act were being pushed by the colleges. I can recall with vividness the heated dispute with reference to this very question of admission of the homeopaths and eclectics to proportionate representation. It was thought to be a defilement even to come near unto the unclean thing. But wise counsels prevailed, and representation remained general, as it was, though it is true, I believe, that the eclectic body no longer has practitioners enough in the Provinces to send a representative.

The influence which this organization has exerted has been in the highest degree beneficial, and the schools now accept the inevitable with a perfectly good grace. The Board possesses a magnificent central building in which to conduct the examinations, with offices for registration and rooms for a Provincial Library. The fees from the examinations and a small annual tax levied on each registered practitioner has proved a source of ample income. The same condition, with modifications, exists in the other British Provinces.

To those who look upon such a scheme as I speak of as Utopian, and urge difficulties on account of the deeply-seated prejudices and wide dissensions existing between the schools, I might say that the condition here is practically the same in kind, though perhaps greater in degree, to that which existed in the British Provinces prior to 1866. What has been done there so successfully can be equally well accomplished in every State of the Union.

The great gain is, the public guarantee that when a man has received the license to practice, he has, at any rate, the elements of a solid education; that he knows the structure and functions of the human body; and that he is capable of meeting the ordinary emergencies of professional life. Such a plan removes the irresponsibility of the schools, establishes a uniform curriculum of studies in each, and exacts a minimum time for theoretical and practical work.

The difference is simply this, that under our present system independent and irresponsible schools have the upper hand and dictate terms to the profession and to the public, and do whatever they please. With an organized profession, through its representatives in session, the schools take the second place—they exist for the profession and the public. There can be no question as to the great superiority of this method. It is essentially democratic, and should commend itself in every particular to the profession of this country. It is infinitely superior to the second method carried on at present in many of the States, although the Examining Board nominated by the Governor or the societies are better than unrestricted registration. While the interests of corporations are fully represented in this system, they have not the overshadowing power such as was granted in Great Britain by the recent Act in which it seems almost ridiculous to think that only six representatives from the profession at large found a place in a Board, and this number grudgingly granted as a privilege not as a right.

It does not do, however, to underestimate the difficulties which have to be encountered in any attempt to organize these Boards. It may be premature in many States. The profession, I have frequently heard it stated, are not ready for this. This, from my own observation, I should

doubt. I believe the general body of the profession when it fully understands the question cannot but agree that the method is in reality a safe one. I am sure that the public, through the press, will heartily concur in any plan which will guarantee that the practitioners to whom they entrust life and limb shall be educated men.

Opposition will be strongest on the one hand from the schools, which look askance at any measure likely to interfere with their prerogatives, and on the other hand the members of the homeopathic and eclectic fraternity, not unnaturally, dread lest in any such arrangement a full measure of justice should not be meted them.

The antagonism of the schools is not, I believe, serious. To be effectual they would have to be united. It is notorious that many of the Faculties, or perhaps, more truly, many of the prominent members in each Faculty, urgently support State Boards, and a return to the old and normal condition in which a university degree partook somewhat of the nature of an honor, and had no relation to the license to practice. The opposition from the homeopaths and eclectics need not be serious. They profess to seek for better things and to look for a higher standard of examination. If we are truly anxious to deal fairly with them in a matter, not relating so much to our own as to the interests of the public, I am quite sure that we shall find them ready and willing to join hands in such a laudable work. Nor must we talk to them of concessions, but acknowledge plainly their rights, which before the law are the same as our own.

To move surely we must move slowly, but firmly and fearlessly, confident in the justness of our claims on behalf of the profession and of the public, and animated solely with a desire to secure to the humblest citizen of this great country in the day of his tribulation and in the hour of his need, a skill worthy of the enlightened humanity which we profess, and of the noble calling in which we have the honor to serve.

THE BETA-NAPHTHOL VS. HYDRO-NAPHTHOL CONTENTION.

Read in the Section of Therapeutics, at the Meeting of the British Medical Association at Glasgow, August, 1888

BY JOHN V. SHOEMAKER, A.M., M.D.,
OF PHILADELPHIA, PA.

"Who shall decide when doctors disagree?" says the poet, with as close accordance with a general truth as reason and poetry require. Yet we shall always find, even in the case of the disagreement of doctors, criteria by which rational decision may be reached. In the first place, the opin-

ions of individual doctors, as well as of persons not doctors, are not of equal weight, as emanating from men of learning, conversant with the class of subjects under consideration, and qualified to be experimentally satisfied, if question of experiment there be, of the results which they have obtained. In the next place, personal feeling and pecuniary interest may enter into the determination of questions and, giving bias, place the decider of them in a non-judicial attitude of mind. Other things being equal, the fact of the majority, and that a large majority, on one side, is an element enabling an outside investigator to reach, even amidst a mass of conflicting testimony, a verdict by which he can abide. If, in addition to acceptance of the truth of a proposition upon these general principles, we ourselves have personally investigated a subject susceptible of the test of experiment, have faithfully experimented, and have found our results to coincide with all that has been deduced by the majority of unbiased eminent experts, it is impossible for the mind to rest more securely in conviction. And this is the confidence, I confess, in which my mind reposes with reference to the contention regarding the respective merits of beta-naphthol and hydro-naphthol, for the reason that it rests upon the foundations described.

I have for several years used beta-naphthol in my practice, and coincidentally have kept myself informed with regard to the investigations of it going on in both Europe and America, growing out of the discussion concerning the relative merits of beta-naphthol and hydro-naphthol.

My first printed contribution to the subject was read on October 17, 1883, before the Philadelphia County Medical Society, and published November 3 of the same year, in *THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION*. My second paper was a brief one, published editorially in *The Medical Register*. My third paper was read at the late meeting of the American Medical Association in Cincinnati, and appeared in *THE JOURNAL*. In the first of these papers, written on the basis of a statement of chemical analysis by Dr. Justus Wolff, I cited many instances of treatment in my own practice with beta-naphthol, both of administration of the drug to myself personally and to patients, adding testimony in its favor from the practice of other physicians; everything pointing to the fact that it is not especially toxic in character.

The gist of my second paper was that, as Dr. Justus Wolff had gone over to the enemy, and as the contention regarding the toxic character of beta-naphthol seemed to be leading in America to little determinate results, the best way to settle the question was, I thought, to subject the action of the drug to a trial from the results of which there could be no evasion.

The third paper entered more fully into the

subject, and made one suggestion as to the cause of the impurity of hydro-naphthol. Curious to relate, it is this hydro-naphthol, which has been shown to be an impure form of beta-naphthol, that is upheld by its advocates to the disparagement of its purer representative. Now arises a question of circumstantial evidence. Who are the chief supporters of hydro-naphthol as against beta-naphthol? Undoubtedly, those persons in New York having a sort of proprietary interest in the manufacture of hydro-naphthol, and to them must be added that class of physicians which obtain their information as to new preparations from hearsay and from advertisements; the class which, having its counterpart in every profession, is that which is readiest to give certificates of excellence. It may moreover be cogently asked, What name but one, prominently associated with chemistry is also associated with the laudation of the quasi-proprietary hydro-naphthol of New York? And lastly, we may well think it strange, that this excepted chemist seemed to ascertain the poisonous character of beta-naphthol simultaneously with his discovery of hydro-naphthol, and yet that would not seem to enter into the chemical constitution of the new discovery. These facts are strange coincidences if they are mere coincidences, and do not point to underlying facts.

For the sake of argument, however, reckon them, if one will, mere coincidences, and let them be acquitted of ulterior significance if they can stand being contrasted with the facts to be mentioned. Some of the most eminent of living chemists, men who cannot by any possibility be shown to be biased in the slightest degree, either as to beta-naphthol as compared with hydro-naphthol, or as to anything else, save as concerning the searching for, finding and promulgation of the truth, emphatically declare, under the signature and seal of their own great reputations, that the vaunting of hydro-naphthol as what it has been affirmed to be by its advocates is erroneous, and as what it has been affirmed to be, in comparison with beta-naphthol, as erroneous again.

If these allegations are correct, decision must be rendered on both counts against hydro-naphthol. Mr. Merck, of Darmstadt; Professor Jacobson, of Berlin; M. Bouchardat, of Paris; the physicians of the Pathological Institute of Giesen, Germany; and Drs. Hoffmann and Endemann, of New York, represent either directly or inferentially the opponents of hydro-naphthol; and have all given the most conclusive reasons for our rejection of it.

It has been shown by them that, barring the impurity of hydro-naphthol, the difference in chemical constitution between it and beta-naphthol is *nil*. In the *Pharmaceutische Rundschau*, of New York, we Americans find, either in the original or republished form, much bearing upon the subject. In Vol. V, No. 4, p. 82 of that jour-

nal there is a long article from Mr. Merck, regarding what he describes as the so-called hydro-naphthol. In Vol. V, No. 7, p. 154 of the same journal, there is another article by him. In the first of these he gives us two pages of discussion of the subject, chemical constitution, experiments on animals, etc., concluding with the expression that danger from the application of beta-naphthol instead of hydro-naphthol is out of the question, unless it be to the profits of those interested in hydro-naphthol; that in regard to this danger it is, in the meanwhile, well for the public to know, so that no one, through ignorance of the true state of the case may be deceived by employing the falsely named, impure beta-naphthol instead of the pure ones; and that, the chemical and physiological identity of beta-naphthol with the so-called hydro-naphthol being well known, Seabury & Johnson, whether wittingly or unwittingly, have placed on the market an impure beta-naphthol under another name.

Returning to the charge, in the second article noted, Mr. Merck says flatly: "I have in this affair here said my last word, and confidently trust that thanks are due me for having contributed to the clearing up and settling of the hydro-naphthol swindle." Nothing but an *embarras de richesse* in Mr. Merck's two articles prevents me from drawing at length upon the evidence which he gives in support of his severe conclusion.

In Vol. VI, No. 2, pages 40 and 41 of the *Rundschau*, we Americans also found republished Professor Bouchardat's investigations, which are summed up in the *Pharmaceutical Record* substantially as follows: Beta-naphthol is absolutely safe in any form that it is likely to be administered. Experiments on animals prove conclusively that it would require nearly $\frac{1}{2}$ lb. of it taken internally to produce fatal results in a healthy person weighing 150 lbs. Tested by injected into the veins of animals, as a 1 per cent. solution, the amount determined as requisite to produce death in adult human being of 150 lbs. weight, was 400 grains.

Ten grains in a quart of water will prevent the growth of any organisms. It has five times the antiseptic power of carbolic acid, four times that of creosote, three times that of iodoform, five times that of iodol, four times that of naphthalin, but has only one-twentieth the destructive energy of biniodide of mercury.

Dr. Jacobson is to be found on the same side, equally determined not to lend, even by silence, countenance to a deception of the less educated among the medical fraternity, and through them, of the public. Drs. Hoffman and Endemann, writing in America, are of course best known to such physicians in that country; but if their weight is disputed, that of the other authorities cited can certainly not be impugned. I shall be forgiven, with such authorities as I have on my side, as compared with those on the other side, for

adhering to my convictions as to the merits of beta-naphthol as compared with hydro-naphthol. Contrast the following lucid statement by Mr. Louis Genois, in the *Medical Times* (American), of June 15, 1888, with that which follows it, from the pen of Dr. Justus Wolff in the *International Journal of Surgery and Antiseptics*, of April, 1888.

"Naphthols," says Mr. Genois, "are compounds derived from naphthalin by the substitution of one molecule of hydroxyl (HO) for one atom of hydrogen.

"Naphthalin is regarded as a derivative of benzol, its graphic formula representing it as two benzol rings adhering by one side. The hydrogen atoms of naphthalin are divided into two groups, in one of which they are written with a small h, and in the other with a capital H. Now, derivatives of naphthalin in which the (small) hydrogen atoms are replaced by other elements or radicals are called alpha derivatives, (such are compounds containing chlorine, bromine, nitric acid, etc.), while those in which the (capital H) hydrogen atoms are replaced by other elements or radicals are called beta derivatives. When, however, naphthalin is treated with sulphuric acid, both varieties are produced, unless very elevated or long-continued heat be applied, in which case only the beta variety results. The usual method of manufacture is as follows: Naphthalin and sulphuric acid are heated together for several hours, the mixture poured into a large quantity of hot water, the excess of the naphthalin filtered off, and the solution saturated with lead carbonate. On evaporation the beta salt crystallizes out first, the alpha salt last. The former is soluble in boiling alcohol, the latter is not; hence they are easily separated.

"From these lead naphthalin sulphonates the respective acids are prepared, and from the acids fused with an alkali, two naphthols are made—the alpha and beta, and these are the only possible naphthols. Dr. Justus Wolff, however, tells us, in his paper, above mentioned, that he has, besides the two well-known alpha and beta naphthols, met with two more naphthols similar to the above ones, but distinct from them in their chemical constitution and some of their properties and reactions. He says the four naphthols, then, are as follows: Alpha-hydro-naphthol, alpha-anhydro-naphthol, commonly called alpha-naphthol, beta-hydro-naphthol, named in commerce (that is named by himself), hydronaphthol, beta-anhydro-naphthol, called in commerce beta-naphthol."

Here is a case of disagreement among doctors, with a vengeance. Physicians quote M. Bouchardat against Dr. Justus Wolff, and in this very article Dr. Wolff quotes M. Bouchardat as verifying his results. Mr. Louis Genois informs us

that alpha and beta are the only possible naphthols, and Dr. Wolff says he has found four.

How is one to know, in these mysterious days, what is true and what is false in even chemistry? Perhaps there is some capacity in matter, even when not tenanted by mind, to cast its astral and other psychical body in a quite fortuitous manner, never to be resumed, even to the view of one versed in the most occult mysteries of esoteric Buddhism; and perhaps these hydro things may never turn up again, or perhaps they may gradually materialize from the ghost of print.

The situation amounts simply to this, that physicians who vaunt the superiority of the so-called hydro-naphthol over beta-naphthol betray their ignorance of the literature of the subject, of the fact that some of the most distinguished of living chemists have given conclusive evidence of its being an impure form of beta-naphthol, and that no one of equal authority has testified to the contrary, while at the same time there is every reason to believe that the heralding of the so-called hydro-naphthol as a genuine article, superior to every similar product in the market, is purely a commercial speculation.

My own investigations on the subject, necessarily confining themselves to the questions of reaction and physiological effects, and covering many years, have proved conclusively to me that the opponents of beta-naphthol know nothing of the subject except through venders of hydro-naphthol, whose procedure Mr. Merck well characterized in a single word. Supported in my own conclusions by the able investigations that have taken place in Europe, supplemented by those of some of my own countrymen, I am perfectly satisfied to rest the case with its mere statement.

HYDROCELE OF THE HERNIAL SAC.

Read before the Medical Society of the District of Columbia, January 10, 1888.

BY THOMAS M. NORTON, M.D.,

OF WASHINGTON, D. C.

R. H., of this city, male, æt. 6 years, came under my care July 26, 1888, the following history being given by his mother: Several days previous he had fallen from a tree, but hung to a lower limb by his clothes and hands until she could run out and take him down. He complained of pain in his left groin all of the afternoon, lying down most of the time; and on putting him to bed she found a small tumor at the spot where pain was located. But thinking he had simply bruised himself, she felt no uneasiness. The next morning the tumor had disappeared; returning, however, soon after he arose, though giving him no pain. It remained all day, subsiding again during the night. Such conditions continued for several days, when she noticed the tumor was

gradually increasing in size; then for the first time becoming alarmed, called me to see him.

Examination revealed a small direct inguinal hernia, which issued from the external abdominal ring and extended about halfway to the bottom of the scrotum. Impulse on coughing was well marked, and the hernia could be easily reduced by taxis, giving forth on reduction the peculiar hernial "slip" or "flop." The gut passed through the external ring directly backwards into the abdominal cavity, not following the course of the inguinal canal to the internal ring, as it would in an indirect or oblique inguinal hernia.

It is probable the hernia had been forming behind the external ring for some time past, and was merely forced through that opening by the strain to which patient had been recently subjected. I sent him to a truss maker, who fitted him with a truss which perfectly retained the rupture. It inconvenienced him for a day or two until he became accustomed to the pressure, after which it gave him no trouble. He remained under my observation for two weeks, at the end of which time he had resumed all of his former habits, running around and playing with the neighboring children just as he had done before the appearance of the hernia.

About the middle of August he accompanied his mother to Boston, and I heard no more of the case until September 2, when I was again called to see him. His mother informed me that, a few days after arriving in Boston, he had complained one evening of the truss hurting him, but she, thinking it imagination, had made him sleep in it that night. The next morning she found the groin very much inflamed and swollen, being quite painful to the touch, and concluding the truss had slipped out of place, she readjusted it and allowed him to get up, but the pain soon becoming so intense, she was compelled to remove the truss and put him to bed. The inflammation continued for several days, but gradually subsided, leaving, as she thought, the hernia just as it was before, excepting that it did not go in during the night as it had previously done. His bowels were open all of the time, and his appetite was good, his food causing him no inconvenience.

On examination I found a small semi-elastic, irreducible tumor, about the same size and shape and occupying the same location as the hernia. Impulse on coughing was absent, nor was the tumor influenced in any way by straining movements and changes of position on the part of patient.

As there was no history of constipation or interference with the digestive organs, obstructed and strangulated herniæ were excluded, hence the diagnosis lay between hydrocele, varicocele, enlarged inguinal gland, and hæmatocele. For as both testicles were in place, undescended testis was not taken into consideration.

The regularity of the surface of the tumor, its unchangeableness when patient was in recumbent posture, and the absence of the characteristic "cordy" feeling, excluded varicocele. Its position and shape, together with the history of the case, antagonized a diagnosis of enlarged inguinal gland. When examined by artificial light the tumor was translucent, thus differing from hæmatocele, which is opaque under artificial light, as is also an enlarged inguinal gland, therefore the diagnosis of hydrocele was clear. The question then naturally arose as to whether I had mistaken a hydrocele for a hernia in the first instance, but a comparison between the former tumor and the one now present dispelled any such idea.

The first tumor gave a marked impulse on coughing, did not fluctuate on palpation, was reducible and easily retained when reduced, but returning on the removal of the obstruction, and on reduction gave forth the "gurgling" sound which characterizes a hernia; while the second tumor was irreducible, fluctuated when palpated, gave no impulse on coughing, and was translucent under the "light test."

Dr. Geo. B. Harrison kindly saw the case with me on the following day, and together we diagnosed it "hydrocele of the hernial sac." It differed from hydrocele of the tunica vaginalis or ordinary hydrocele in that this commences, as a rule, at the bottom of the scrotum and progresses upward, gradually filling the entire scrotal cavity, while the hydrocele under observation extended from the external abdominal ring to only about the middle of the scrotum, having a separate and distinct sac around which the scrotum could be freely moved.

Diffuse hydrocele of the cord extending into the scrotal cavity resembles this, but the history of the case contraindicated that affection. Moreover, in hydrocele of the cord, when examined by artificial light, the cord is seen in the tumor, and the contents of the tumor can be pressed back into the inguinal canal, returning again on the removal of the pressure; while in the case of the hydrocele under consideration the cord could be felt behind its sac external to and distinct from it, and could be traced from the testicle up to the external ring, thence into the inguinal canal beneath the neck of the sac, and no force could squeeze the contents of the tumor into the inguinal canal.

In encysted hydrocele of the cord, which is sometimes found in this location, any movement of the testicle or cord is reflected upon the hydrocele itself, and the absence of this peculiarity excluded that affection.

Advised by Dr. Harrison, I evacuated its contents with an aspirating needle, and with strips of adhesive plaster and a thin sheet of rubber placed a light compress over the sac. This was repeated several times, the sac refilling after the

operations. About twelve weeks ago, after drawing off its contents, I washed out the sac with a 2 per cent. solution of carbolic acid, since which time the hydrocele has shown no tendency to return.

The literature on this subject, so far as I have been able to ascertain, is rather brief and unsatisfactory. Drs. McArdle and Kolipinski, after carefully perusing the works of foreign as well as American authors, found recorded but twenty-nine authenticated cases of dropsy of the hernial sac. My own incomplete researches have been far less satisfactory. Wyeth, Ashurst and Erichsen mention the affection as occasionally occurring, and dismiss the subject in a very few words. Gross touches it lightly under the head of hernial hydrocele. Bryant speaks of it as a rare affection, having himself experienced but one case, which occurred in a man of 40, who for two years had been treated for hydrocele of the tunica vaginalis, and where the true diagnosis was only discovered upon post-mortem examination. Agnew, in dealing with the subject, makes the following assertion: "The neck of a hernial sac may become obliterated either from the long continued pressure of a truss, or by a portion of its contents becoming adherent to its mouth. The pouch below, being a serous structure, may become inflamed and dropsical." Accepting this statement as correct, I think the mechanism of the change from a hernia to a hydrocele in the case just reported admits of a plausible explanation.

From the anatomy of the inguinal hernia we would naturally expect to find the most constricted portion of its sac at the external abdominal ring, just as it passes between the tendinous columns which form the lateral boundaries of that opening. At the base of this opening is found the crest of the pubes, presenting a hard bony resistance against the pressure of the truss. Now the delicate tissues of the child, constricted on one side by this bony wall and on the other by the truss, became inflamed. The hypertrophied parts pressing together the sides of the corrugated neck, caused the folds to unite, thus obliterating the sac from the abdominal cavity; and the inflamed lining membrane of the sac becoming dropsical, furnished the contents of the hydrocele.

THE GEOGRAPHICAL DISTRIBUTION OF RICKETS AND CHOREA.—The report of the Collective Investigation Committee shows that rickets, though not unknown in rural regions, is mainly a disease of towns and industrial regions, and especially of large industrial towns. Chorea, like rickets, is mainly a disease of towns and industrial regions, though by no means unknown in rural districts. Its distribution is affected by that of acute and subacute rheumatism, its prevalence diminishing as the latter disease becomes rare.—*Lancet*, Jan. 19, 1889.

SURGICAL CLINICS AT THE WESTERN PENNSYLVANIA HOSPITAL BEFORE THE STUDENTS OF THE WESTERN PENNSYLVANIA MEDICAL COLLEGE.

BY PROFESSOR J. B. MURDOCH,

SURGEON TO THE WESTERN PENNSYLVANIA HOSPITAL AND PROFESSOR OF CLINICAL SURGERY IN THE WESTERN PENNSYLVANIA MEDICAL COLLEGE.

[Reported by WILL. N. PRINGLE, M.D., a member of the Graduating Class.]

October 20, 1888.

OPERATION ON A FROST-BITTEN FOOT.

We have here a patient who has had his foot frost-bitten, from which he has lost one toe by amputation, and another one has fallen off, leaving a large and very painful cicatrix. It is not many years since surgeons amputated the leg for injuries involving only the foot. It is not over fifty years since the distinguished French surgeon Velpeau advised amputation at the point of election, as it was called, for such injuries. The point of election was a point about a hand's breadth below the knee. This I suppose was owing to the fact that artificial limbs were not so well known or so much used as they are to-day, and because they only had such artificial limbs as they could use by resting the knee in a flexed position on a wooden one, allowing the stump to protrude behind. But since those days about twenty-seven different amputations have been done between the toes and the ankle-joint, chief among them being those of Hay, Chopart and Syme.

Mr. Hay's amputation is that done between the tarsal and metatarsal bones, while Mr. Chopart's amputation separates the tarsal bones, and hence is sometimes called the medio-tarsal operation. Mr. Symes' operation is done at the ankle-joint. Now all of these are good operations, but the proper operation must be adapted to the proper case; it would not be a right thing to do a Chopart's operation if a Hay's would answer as well, nor would it be proper to do a Symes' if a Chopart's operation would do as well, and if in a given case you can do a better operation than either of them there is no reason why you should follow any of them. They all have their disadvantages as well as advantages. In Chopart's amputation one disadvantage, in the eyes of many surgeons, is that all of the muscles of the anterior part of the leg are severed, thus leaving no antagonist to the action of the gastrocnemius muscle, which, by contracting, raises the heel from the floor, turning the top of the foot down, causing the patient to walk on the cicatrix. I only advise this operation where you can get a long plantar flap and need no dorsal flap. Another objection is that the arches of the foot are destroyed, and consequently the spring and elasticity is gone. Some one has said that if the tread of the foot is lost that the

amputation had better be made at the ankle-joint, because the patient must limp in any case, and that he will be able to do better work by losing the entire foot.

This is not my advice. My rule is always to save as much of the foot as I possibly can. You will find that the mortality will be less in so doing. In the case before you I will follow no particular rule, I will reflect a superior and an inferior flap, and saw the metatarsal bones off as near the metatarsophalangeal articulation as possible. In studying anatomy many students study arteries, muscles and nerves and throw away the remainder, but the man who does not understand the ligaments, nor appreciate the arches of the foot, will never make an orthopedic surgeon. True, he may be able to do some mechanical operations, but he will never understand the causes of malformations or deformities of the foot. As I remove the Esmarch's bandage I am sorry to say that I see little or no bleeding from the wound. It is a good sign to have more or less bleeding from a wound, it shows that there is vitality there, and it is evidence that there will be repair of the wound. In this, as in all other cases where practicable, I use torsion to control hæmorrhage, so that I am certain that I leave no foreign substance in the wound.

Where ligatures must be used catgut is better than silk, as it is an animal substance and is readily absorbed. It is nevertheless foreign matter, and a very prolific source of septicæmia, as it is very hard to render it aseptic and keep it so. In all cases where an Esmarch's bandage has been used there will be more or less oozing from the capillaries, and the limb should be kept elevated for from one to four hours. The oozing will cease much sooner than if it were left in a horizontal posture. A drainage-tube should also always be used, as a collection of blood and serum may create wound tension and interfere materially with repair. In about one week the drainage-tube will have served its purpose and should be removed, otherwise it becomes a foreign substance in the wound, with all that that implies.

November 3, 1888.

OPERATION ON THE ARM FOR A STAB-WOUND MADE THIRTY YEARS AGO.

We have here another case, that of a man 76 years old. He was injured in a fight thirty years ago, by the stab of a knife, the point entering the elbow-joint from behind. Since that time he has suffered almost continual pain, and it is partly to relieve this pain that we do an operation on his arm to-day. You see the joint is partially ankylosed, swollen, and deformed from chronic synovitis. I will use an Esmarch's bandage on this arm.

I do not know what may be required here until

I open the joint, but I will begin as though I were going to excise the joint. We make an incision 4 inches long on the posterior aspect of the arm and parallel with it. Two-thirds of the incision will be made over the olecranon process and one-third over the base of the humerus, clear down to the bones. The heads of the bones are then dissected out, care being taken not to injure the ulnar nerve, which lies between the olecranon process and the inner condyle of the humerus. We guard against injuring this nerve by keeping the edge of the knife close to the bone. I will remove the olecranon process with the saw and the diseased cartilage with a scraper. As I do this, however, I meet with a metallic substance, which by the aid of the forceps I withdraw with difficulty, and which, as you see, proves to be the rusty and corroded point of what was at one time an ugly, dangerous-looking bowie-knife. It is fully an inch and a half long and one inch wide at the base. It has lain imbedded in the joint of the old man's arm for thirty years, the source of all the pain he has suffered in that arm.

We cannot in a man at this age expect to secure a very useful arm. This wound will, however, I think, heal kindly, and he will have less pain, to say the least, than he has had in the past, which is a result not to be ignored.

As I explained to you last week the difference between a septic and an aseptic wound, you will at once recognize this as a septic wound, because septic materials are already present in it. As there are deep sinuses and pockets filled with this septic matter, you will appreciate the difficulty in getting rid of them. They are like yeast, if but a small number of these germs remain they will promptly multiply and infect all of the wound again. Notwithstanding this, however, we will use all the antiseptic precautions that we would if the wound were an aseptic one and will hope to get good union of the parts and a speedy closing of the wound by nature. I will also place a drainage-tube in the bottom of the wound and the ordinary antiseptic dressing will be applied, and the patient will be removed to his bed in the ward.

December 15, 1888.

REVIEW OF SOME CASES OPERATED ON.

I want to show you to-day some of the cases on whom we have done operations, in order that you may be able to follow them to their termination. The first is the old gentleman 76 years of age on whom we excised the elbow for a stab-wound received thirty years ago. You will also remember that I removed the point of a dirk-knife from the wound which had lain imbedded there for all these years. The arm, as you see, might not be considered a useful arm, but it is still much better than it was before the operation, and he has no pain, which is an item to be taken into consider-

ation. This is the oldest case of excision of the elbow of which I have any knowledge.

Another case I want to show you is that of the man for whom we excised a knee-joint in the early part of the course, this year. You see he is able to walk around and has a very useful limb. He will leave the hospital in a few days. You see, as I manipulate the limb, that there is perfect ankylosis at the knee, the tibia and femur are practically one bone. You have seen several operations of this kind this winter, and they are operations that I think we should feel proud of, because they are much better than amputation, leaving as they do limbs which are so much better than any artificial appliances.

March 2, 1889.

Before bringing a patient before you this morning, let me read to you a letter from our old friend Thomas Cavanagh, upon whom you saw me do excision of the knee-joint early in this session. I read this letter in order to make the history complete.

DU BOIS, PA., Feb. 26, 1889.

Dear Friend:—With the greatest of pleasure I must let you know that I am walking without crutches or cane. It was on the 5th of February that I walked. I was very much surprised at myself when I done it. From the day that you operated on my knee till the day I walked was 4 months and 8 days. How is that for an old man? Therefore I thank you most respectfully for your skillful operation on me. Doctor I must let you know that I have had no pain in it since I left the hospital, and if I live till the 4th day of July I will go and see you. You can use this letter any way you like.

Therefore I remain yours truly,

THOS. CAVANAGH.

Dr. J. B. Murdoch, Pittsburgh, Pa.

MEDICAL PROGRESS.

PHENACETINE.—Apparently one of the best of the modern antipyretics is a substance described by Hinsberg and Kast as para-acetphenetidin, a substance analogous as regards its chemical constitution to antifebrin. We have already a number of times alluded to the properties of this substance (*Therapeutic Gazette*, 1888, pages 43, 142, 699), and although the testimony as to the action of this preparation as an antipyretic and antineuralgic appears to be unanimous as to its value and freedom from danger, it has attracted no attention among English-speaking members of the profession. This preparation, phenacetine, as first prepared, was a reddish, odorless powder, insoluble in water and in glycerine, and thoroughly soluble in hot alcohol and alkaline liquids. It has been recently prepared in colorless, crystalline needles, which are claimed to be soluble in acetic and lactic acids, and in hot oils. Extended experiments on dogs and rabbits have

shown that it is almost inert in doses of from 15 to 30 grains given daily for days at a time. When the dose is increased up to 45 and 75 grains in large dogs it produces accelerated respiration, sleepiness, disturbed coördination, and vomiting, and, in still larger doses, methæmoglobin is produced, as in antifebrin-poisoning. Even after this symptom has appeared, however, recovery has almost invariably occurred. Dr. Hoppe (*Deutsche Medicinal Zeitung*, No. 92) has made a number of experiments on man, administering doses of from 15 to 40 grains, and has found that after a time the system becomes accustomed to the remedy. The only disagreeable effects produced by these amounts were sleepiness, dizziness, nausea, and slight chilliness, the temperature, as consequent on doses of 30 grains, being reduced only a few tenths of a degree Centigrade. It appears, therefore, to be almost free from toxic properties, while his experiments made in the Jewish Hospital in Berlin, have confirmed the result of the experiments as already published by other observers. It has proved absolutely harmless, the only disagreeable after-effect being profuse perspiration, ringing in the ears, followed by weakness, and only in individuals already depressed by disease. As an antipyretic in children, doses of about 2 grains reduce the temperature from 1° to 2° C., a single large dose producing more effect than repeated small doses.

Led by the analogy of phenacetine in composition to antipyrin and antifebrin, Dr. Hoppe has likewise tested the properties of this drug in twenty-five different forms of neuralgia, in the majority of which relief of pain followed its employment. Various cases of headache were also relieved by its use within half an hour to an hour; and he believes that in neuralgia, as in febrile disease, it is equally as efficacious as antipyrin, and is preferable to it on account of its freedom from danger.

Dr. Rumpf (*Berl. Klin. Wochenschr.*, No. 23, 1888) likewise experimented to a considerable extent with phenacetine as an antipyretic and in the treatment of neuralgia. Dr. Rumpf believes that as an antipyretic it is as active as any yet introduced, since he has found that a single dose of 15 grains given to adults may reduce the temperature in the febrile state from two to three degrees in two hours; even half the dose has produced the same effect with no disagreeable complications. In eight cases of hemicrania doses of 15 grains produced great relief, while in seven cases of neuralgia of different nerves it has likewise been very satisfactory. Dr. Rumpf describes phenacetine as a drug which, in doses of 15 grains to adults or 3 grains to children, is an absolutely safe, reliable, and satisfactory antipyretic; while in doses of 15 grains it is highly recommended as an antineuralgic remedy in all cases of vaso-

motor neuroses, in the lancinating pains of tabes and the neuralgias of chronic neuritis.

Drs. Misrachi and Rifat (*Bulletin Gén. de Thérapeutique* June 22, 1888) have confirmed in all respects the statements which we have already published as to the action of this remedy. It is these authors who have determined the solubility of phenacetine in lactic acid. They have found that this solution is not disturbed by the addition of water as long as the temperature does not fall below 33° C. It is evident that this discovery is a great addition to the practical value of this remedy, since its high insolubility has been the principal objection to its use in therapeutics. After the administration of the lactic acid solution it is rapidly absorbed, and has been capable of detection in the urine.—*Therapeutic Gazette*, March 15, 1889.

BAKTERIOSKOPY AS AN IMPORTANT CRITERIUM FOR THE DIAGNOSIS OF MENINGITIS CEREBRO-SPINALIS.—PROFESSOR BOZZOLO, in the Reale Accademia di Medicina in Turin, makes an interesting communication which shows how bacteriological investigation may become an important aid in clinical diagnosis. The case concerned a man 54 years of age, suffering from acute fever with chills, from icterus, pains in the back of the neck, delirium and vomiting; the patellar reflexes were missing, and the spleen and liver were enlarged. The existence of pneumonia was excluded by the lack of the necessary physical symptoms in the lungs. On the ninth day of the disease an explorative puncture of the liver was made; by the cultures made with the extracted blood and by vaccinating mice and rabbits the presence of the diplococcus pneumoniae was proven. Thereupon the diagnosis "meningitis cerebro-spinalis" was made. Patient died, and the post-mortem confirmed completely the diagnosis. Besides a diffuse meningitis there was endocarditis of the aortic-valves and abscesses of the liver in consequence of biliary calculi. Bozzolo emphasizes the importance of bacteriological investigation of the blood in doubtful diagnosis, and mentions a very simple method of investigation invented by his clinical assistant Dr. Belfanti, which makes it possible to recognize to a certainty, the presence of the diplococcus in the blood of patients. It consists in the following: By tapping a vein, a small quantity of blood is taken from the patient, transferred to a thermostat, heated to 37°, and left in it for ten or twelve hours. If the diplococcus existed in the blood, numerous colonies of this microorganism will be seen developing on the coagulum.—*Internationale Klinische Rundschau*, 1889, No. 13.

TWO CASES OF FRACTURE OF THE SPINE TREATED BY TREPHINING.—MR. HERBERT ALLINGHAM at a meeting of the Medical Society of

London, read notes of two cases treated at the Great Northern Hospital last year. J. A., æt. 31, was admitted in July, having fallen 40 feet, causing a fracture of the spine. He was paralyzed from below the level of the ensiform cartilage. As he did not improve, in fact, seemed to lose ground, Mr. Allingham trephined the spine through an incision ten inches long. It was seen that the lamina of the sixth vertebra was badly fractured and depressed. He therefore with the bone forceps snipped off the laminae and spinous processes of the fifth, sixth, and seventh vertebrae, exposing the cord for about four inches. The operation took an hour and a half, and the wound was dressed antiseptically. Healing had taken place in about ten days, and the symptoms of ascending changes checked. Some amount of improvement subsequently took place, the level of the paralysis being brought down to the umbilicus. Case 2 was brought to the hospital in August, on account of a fall. She was paralyzed from a level seven inches above the umbilicus. Six days later Mr. Allingham removed the spinous processes and laminae of the third, fourth, fifth and sixth vertebrae, and as the cord was found to be crushed the dura mater was opened. The wound healed up except in the track of the drainage-tube in about a fortnight. The patient, a woman, died seven months later from bedsores, cystitis, etc. The cord was found to be almost divided, both ends tapering down to a fine point. Mr. Allingham concluded (1) that by timely trephining inflammatory ascending changes were prevented; (2) that no bad symptoms followed the laying open of the spinal dura mater; (3) the operation, although tedious, was not difficult, and did not lessen the chance of recovery. DR. MACKENZIE said the fact had recently been established that the spinal column could be opened and examined without much danger, and, where nothing was discovered, the injury inflicted was capable of rectification and the patient was given the best chance of recovery. That was of far more importance than the success of the first two or three operations, since it established the principles upon which future progress could be accomplished. He suggested that Dr. Beevor might be able to elucidate the changes that had taken place in the cord, which were relieved by the operation. DR. ROUTH mentioned two cases in which effusion into the spinal canal had been diagnosed, and in which death had taken place because no one was prepared to undertake to tap the canal. DR. BEEVOR alluded to the difficulties that arose in consequence of the fact that the anesthesia began much lower down than the seat of injury would lead one to suppose. The same difficulties had been met with when Mr. Horsley operated for the removal of a supposed spinal tumor. He said that the question as to the points in the cord at which the sensory fibres

were given off required elucidation. He mentioned a case in which it was clearly shown that the nerves of tactile sensation were distinct from those which conveyed painful impressions. MR. BALLANCE said he was present at the operation performed by Mr. Horsley, and mentioned the difficulty which had arisen from their not knowing the precise spot at which the sensory nerves were given off from the cord. That point had since been worked out by Mr. Shattock and others, and they were fairly agreed at present as to their origin. In Mr. Horsley's case he removed the laminae of four vertebrae without finding anything, but on the removal of a fifth they fortunately came upon the tumor, and the operation had proved successful. He congratulated Mr. Allingham upon the results he had obtained. He himself had seen a good many cases of fracture of the spine, but he had not treated them in the way suggested by the author. He observed that the great difficulty was to know how far the cases would recover without any interference. He supposed that Mr. Allingham would not advocate the operation being performed at once and in every case. He thought the safest plan would be to immobilize the fracture by a plaster-of-Paris jacket for a few days, until they could see what improvement was likely to take place. MR. ALLINGHAM, in reply, said he would have liked to see the cases mentioned by Dr. Routh. He had been struck by the fact that the operation did not affect the patient injuriously in the slightest degree. With reference to the time of the operation, he said he thought it ought to be done early, and his plan was to wait—say a week—and, if no sign of improvement was manifested, to operate. Delay always led to changes being set up in the cord.—*British Medical Journal*, April 13, 1880.

CHANGES IN THE BONES IN OLD AGE.—In the *Illustrated Medical News*, March, 1889, page 193, Prof. HUMPHREY contributes an article on the changes in the bones in old age, and illustrates his remarks with some valuable illustrations. To the naked eye these changes consist in an absorption of the cancellous structure, commencing in the parts which are most cancellous, that is, where the bony plates are thinnest, where the marrow is most abundant and most vascular, where the leucocytic and other agents in absorption are most abundant, where, accordingly, we might expect the processes of absorption to be most ready to take advantage of any failure in the nutritive and resisting qualities of the bony tissue. In the early condition the several parts of the skeleton are solid; as they become hardened and added to at the exterior, they become hollowed out in the interior into cancellous spaces, medullary canals, and air-containing cavities; this change continues through life in gradually diminishing degree; and

as old age advances, the subtraction from the interior exceeds the addition to the exterior, and the bones gradually decrease in weight and strength. The muscles at the same time become weaker, so that it is almost as rare to have a spontaneous fracture of a bone from muscular action in old age, as it is in youth or middle age. The author shows by diagrams how in old people the head of the femur becomes thinned and liable to fracture. This predisposition to absorption in the cancellous parts is met with in the ends of the long bones in all aged people, which causes their liability to fracture. The tendency to absorption of the cancellous parts of the skeleton is also seen in the alveolar processes of the jaws, whereby the teeth are loosened and often drop out. In the body of the lower jaw these changes are very marked; the thin lower bar alone remains with the mental foramen upon or near the upper edge; in the upper jaw alveolar processes become, in course of time, completely cleared away; the level of the palate is continued to the margin of the bone, the whole maxilla (the walls of the antrum more especially) becomes very thin, and the nasal spine and the cheek-bones are left outstanding in relatively strong relief. An exception to the progressive cancellous absorption and diminution of weight in the bones of old people is not unfrequently to be found in the skull, more particularly in the calvarium. This part in some cases becomes very thin and light; in others it becomes thicker from deposit on the interior consequent probably on the lessening of pressure upon it associated with the brain-shrinkage of age; in some of these latter cases it is very porous, the dioplœ being increased; in others, however, it is dense and heavy, as well as thick, the dioplœ being encroached upon and perhaps obliterated. The contrast in some cases presented by the thick heavy calvarium, and the thin light facial bones, is very striking; the skull of many old people weighing many ounces over the average, and this is due to increased thickness and density of the bones enclosing the cranial cavity. This senile thickening and "senile sclerosis" differ from the changes in osteitis deformans, inasmuch as they affect the interior of the skull and the dioplœ rather than the exterior. So far as the author knows, the cranial wall is the only part of the skeleton in which this process occurs. The increased density and weight of the skull when the rest of the skeleton is becoming less fitted to bear weight is a strange and not easily intelligible anomaly.—*London Medical Recorder*, April 20, 1889.

THE DURATION OF LIFE IN CANCER OF THE BREAST.—The average duration of life in cases of mammary carcinoma is very variously estimated by different observers, ranging from 28 to 55 months in those not operated upon, and from 32 to 53 months in cases in which the new growth

has been removed by the knife. Thus Gross, whose statistics are among the least hopeful, gives as the average duration of life, of those in whom the disease had been permitted to run its course, 27.1 months, and of those operated upon about 39 months. Sibley's figures for the same classes of cases are 32.25 and 53.2 months. Baker makes the average, for cases uninterfered with by operation, 43 months, while Paget's estimate for the same class of cases is 55 months.

By far the most hopeful figures which we have seen are some given by Mr. W. R. Williams, in *The Lancet* of January 12, 1889. He has recorded and tabulated all the fatal cases of cancer under treatment at the Middlesex Hospital during the last six years, with the result that the average duration of life, dating from the time when the disease was first noticed, was 60.8 months for those who had undergone operation, and 44.8 months for those in whom the disease ran its natural course. The longest duration of life when the breast was amputated was 297 months, and when no operation was performed 194.7 months. The author thinks that his statistics justify surgeons in taking a less despondent view of mammary carcinoma than is ordinarily taken.—*The Medical Record*, March 30, 1889.

CHARCOT ON SUSPENSION IN THE TREATMENT OF PROGRESSIVE LOCOMOTOR ATAXY.—PROFESSOR CHARCOT recently gave a clinical lecture on vertical suspension of the body in the treatment of progressive locomotor ataxy and some other diseases of the nervous system. This novel method of treating tabes dorsalis was first initiated by Dr. Motchoukowsky, of Odessa, who published a *brochure* on the subject in 1883; but it received no attention in Western Europe till 1888, when Professor Raymond, of Paris, while on a scientific mission in Russia, was struck with the results presented to him. Dr. Ouanoff, his fellow-traveler (a pupil of the Salpêtrière clinic), showed his practical application there. In Motchoukowsky's pamphlet considerable improvement was ascribed to it in twelve tabetic persons; also in various neurasthenias, independent of tabes, in which the sexual functions were reëstablished by this treatment. The patient is suspended for about three minutes by a Sayre's apparatus, and the arms of the patient while suspended are raised every fifteen or twenty seconds to increase the traction on the spinal column.

Charcot's tabetic patients numbered eighteen, with 400 *séances*. Of these, four were only suspended each three times; the rest went on regularly. Of these Professor Charcot says: "The remaining fourteen have experienced in varying degrees an improvement, which in eight has been quite remarkable." All were pronounced tabetics.

Walking is improved to begin with; the patients say they can walk better after the first suspension. This improvement at first lasts only a few hours, but after eight or ten sittings persists. After twenty or thirty sittings Romberg's sign disappears. Then vesical troubles are lessened or removed; also the lightning pains. Sexual impotence gives place to sexual desires and erections. (Experiments by Dr. Ouanoff on healthy persons have shown that this method has an exaggerating effect on virility.) The cotton-wool feeling in the feet gives away more or less to healthy sensations, and in general the whole health improves. Every patient steadily improved, with one exception, a young tabetic, aged 32, who at first improved, then fell off, then again improved somewhat. But the knee-jerks have not reappeared in any of the patients after three months' treatment, nor are the pupillary symptoms altered. As to other diseases, a young female with Friedreich's disease was greatly improved by the treatment. In two neurasthenic and impotent patients the sexual functions were reëstablished. But a patient with disseminated sclerosis was made worse, for after two sittings a spasmodic paraplegia appeared, which, however, gave way in three days. Further trial of this method is required before an opinion of its value can be given. The results are most encouraging so far, and at any rate perfectly harmless.—*London Medical Recorder*, March 20, 1889.

ON THE TREATMENT OF RENAL COLIC.—DR. CHRISTOPH, of Constantinople, was called, some time ago, to the wife of a Jewish banker, who suffered from renal colic and had been treated for three months by the best physicians with chloral hydrat, antipyrin, morphia and lythium benzoate. The woman is 23 years of age, weak, without children although married three years, extremely nervous, which is inherited from her father, who is afflicted with cramps and nervous diseases. In the urine gravel and calculi were found, which chemical analysis proved to consist of urates. Despite daily doses of 5 centigrams of morphia she had constant pains, which deprived her of sleep during the night, impaired digestion, and still more shattered her nervous system. In view of the unsuccessful analytic therapy he remembered having read in Frerich's well-known work on liver diseases Troussseau's prescription for renal colic, consisting of inhalations of chloroform at every attack of pain. To his agreeable surprise the patient informed him, on a subsequent visit, that she was entirely free from pain after inhaling for twenty seconds, and that she had been obliged to repeat the inhalation only three times during the day. Later on he alternated between this remedy and butylchloral, 5 grams in 120 grams of water, with 10 grams of spir. vini rectif. and 20. gr. glycerine, of which 2 or 3 tablespoonsful

daily, taken quickly one after another, relieved her immediately, or between chloroform and urethan, 3 or 4 gr. daily. To dissolve the stones he added daily 3 teaspoonfuls of magnesia bor. nitr. with sugar dissolved in water.—*Internationale Klinische Rundschau*, 1889, No. 13.

ON SECONDARY INFECTION IN SCARLET FEVER.—DR. MARIE RASKIN, of St. Petersburg, from a series of clinical and experimental investigations, draws the following conclusions: 1. The malignant complications occurring in scarlet fever: lymphadenitis purulenta, phlegmone, otitis purulenta, synovitis purulenta, broncho-pneumonia, pleuritis, pyæmia and septicæmia, perhaps also diphtheria and serous synovitis, are caused by a secondary streptococci infection, other microorganisms possibly having a share in the origin of some of the above processes, as pyogenous staphylococci in otitis and micrococcus pyogenes tenuis in pyæmia. 2. The introduction of the streptococci occurs through the primarily inflamed throat, whence they extend through the lymph channels and thus get into the blood. 3. The streptococci having invaded the blood there are three possibilities: *a*, the cocci may disappear from the blood without any consequences except more or less fever; *b*, they may increase rapidly in the organs and cause death by general septic infection; *c*, often they may cause death by pyæmia. 4. The chain coccus occurring in scarlet fever may be regarded as a variety of the well-known streptococcus pyogenes. 5. It is not the cause of scarlet fever.—*Centralblatt für Bakteriologie und Parasitenkunde*, 1889, No. 14.

ON THE VALUE OF INHALATIONS OF HYDROFLUORIC ACID IN TUBERCULOSIS OF THE LUNGS.—DR. L. POLYAK, in the Society of Physicians in Budapest, declares that by abundant experience with this new mode of treatment, he has arrived at the following conclusions: 1. The bacilli in the sputa increased in every case. 2. The lung-affection grew worse in every case; in three cases the infiltration increased, in two cases considerable disintegration took place. 3. The body-weight decreased in four cases by 0.5–3 kilogr.; in one case it increased by 0.5 kilos., but the other symptoms became worse. 4. In two patients before the inhalations only moderate increase of temperature occurred; during the cure considerable increases in temperature were observed; in a third case the fever increased. 5. In four cases the vital capacity decreased by 100–600 cm.; in one case it increased by 100 cm., although in this case infiltration made progress. 6. The mode of cure is certainly harmful, inasmuch as patients have to stay in a small enclosed room for a long while whose air is not in keeping with the demands of hygiene. From all of which it is seen that these inhalations are not only, not

beneficent, but absolutely harmful.—*Wiener Med. Wochenschrift*, 1889, No. 13.

INCREASE OF BODY-TEMPERATURE AS A PARTIAL SYMPTOM OF VIS MEDICATRIX NATURAL.—DR. DOCHMANN (Kersau) declares that in infectious fevers the increase in body-temperature should not be considered *a priori* as harmful, but that it probably rather contributes to render the infectious virus harmless. He reports independent experiments of his own which seem to support this, so far, but hypothetical view. When cats that had been poisoned with curare, were put into the thermostat and subjected to an artificial increase of warmth, they recovered rapidly from the intoxication, which was not the case in animals kept in a normal temperature. In view of the close toxocological relationship between curare and various ptomaines, the significance of these experiments for the question under discussion cannot be overlooked. Similar results were obtained by Dochmann with animals into whom decomposing substances had been injected.—*Wiener Medicinische Wochenschrift*, 1889, No. 13.

ETIOLOGY OF TETANUS.—M. VERNEUIL, in a paper read before the French Academy of Medicine, dwelt upon the virulence of soil contaminated by the dejections of tetanic horses. He insisted on the frequency of tetanus in wounds of the lower extremities; thus, in Havana, out of 162 patients suffering from tetanus, 132 contracted it from wounds on the legs and feet. The disease is frequent in persons who, after being wounded, get in contact with the soil, as in cases of comminuted fracture, in which the bones are forced into the ground, and crushing of the bare feet; also when earth is used as a dressing, and when the wound is inflicted by an agricultural implement. Experiments made with ordinary soil and soil known to be contaminated strongly support this view. Certain soils seem to preserve their virulence much longer than others, and stagnant water seems to favor the proliferation of the microbe.—*London Medical Recorder*, April 20, 1889.

CANABIN IN GRAVES' DISEASE.—VALIERI, after using cannabin in three cases of exophthalmic goitre, recommends the following formula:—

Cannabin	gr. iv ss
Sugar of milk, q. s.	Mix.
Make 5 pills.	
S. To be taken in 24 hours.	
Cannabin	gr. iv ss
Distilled water	℥ ij
Syrup of orange flowers	℥ j
S. Take in teaspoonful doses in 24 hours	Mix.

Or we may prescribe a decoction of 2 or 4 tooth parts, or doses of ℥ 15 or 30 of the tincture.—*Wiener Medical Presse*, No. 41, 1888.

ETIOLOGY OF INSANITY.

We are indebted to the *Occidental Medical Times* for advance sheets containing a good abstract of the proceedings of the California State Medical Society, in San Francisco, April 17, 18, and 19, 1889. The report of a Committee on Mental Diseases and Medical Jurisprudence, was read by DR. J. W. ROBERTSON of San Francisco, in which he discussed at some length the causes of insanity, and especially the influence of civilization and mental culture. The assertion has been often made that insanity in its various forms, is decidedly increasing beyond the ratio of increase of the population, in all the more civilized countries. But the report says, "if there was any actual increase in the numbers of the insane, relatively, throughout the whole civilized world, statistics have failed to show it." It is suggested that the apparent increase is owing largely to the greater attention given to the insane during the present century. The building of asylums and homes for their humane treatment, and their more careful enumeration in each succeeding census, with less motives for their concealment by friends, have caused the true number relative to the whole population, to be ascertained more accurately. The more detailed and complete census enumerations have also offered better facilities for ascertaining the relations of the various occupations and classes of people. Whether civilization actually exerted any intrinsic influence in the production of insanity, Dr. Robertson expresses serious doubt. The two most prominent factors belong-

ing to higher civilization, are heredity and education with its more intense activities. Regarding the first, it was stated that the records of the Napa Asylum embraced 4,280 cases of insanity, of which 213, or only 5 per cent. were attributed to hereditary influence. Of the whole number recorded at Napa, 2,700 were males, only 33 of whom were professional men, and only 230 who could be regarded as belonging to the educated classes; 450 were classed as artisans, and the remaining 2,000 were laborers or without active occupation, and very largely of foreign birth. It was stated in the report that, "a large foreign population and a large insane population go hand in hand; and the foreigners in this State, (California) who constitute one-third of the population, furnish two-thirds of the insane." Dr. J. H. Brainard, of Los Angeles, stated that he had examined the record of some 8,000 cases of insanity with reference to the influence of education or brain work, and he found that the professions had but a very small representation, the laboring classes being in the proportion of 90 per cent.

DR. G. W. GRAVES, of Petaluma, had been engaged in the examination of persons charged with being insane, for near twenty years, during which time he remembered of but one subject who was a professional man. While the facts given in the report of Dr. Robertson and those elicited in the discussion following the reading of the same, show that in California the ratio of the insane to the whole population is one to three hundred, and that three-fourths of the insane belong to the class of least education and mental activity; the same relative ratios do not prevail in all the States. Yet, it is true in all the States, that much the highest ratio of insanity is found in the laboring classes of limited education, both native and foreign; while the lowest ratio is found in those of the most extended education and most active intellectual work. Consequently it is fair to infer that the progress of civilization, so far as it relates to the development of the moral and intellectual faculties, and the advancement of all the sciences and their application to the arts and the various departments of human industry, has no tendency to derange the mental faculties or to increase any of the forms of insanity. And it is probable that so far as the number of insane has increased faster in population than the increase of population, in this

country, such increase is owing entirely to the large annual immigration from the poorer and least enlightened classes of Europe.

But while the advancement of true civilization with its ever increasing and varied mental activities, affords no proof of being a direct cause of insanity, its influence in strengthening the ambition of even the least enlightened classes for more wealth and better social position without removing from them certain habits and vices that are ever mocking their ambition and defeating their efforts, while stealthily undermining their physical health, may be justly regarded as an efficient though indirect cause of insanity.

There is no condition of the human mind that more strongly predisposes to insanity than protracted *anxiety*, which consists in a more or less intense desire for the accomplishment of a certain object coupled with a constant fear of failure. The ranks of the great laboring classes, especially in this country, are full of individuals and families inspired with the anxious desire to improve their pecuniary, social and educational condition, but whose baser passions and vicious indulgencies either absorb so much of their earnings or tempt them into such unlawful acts, as not only disappoint and disgrace the man, but send the arrows of long dreaded disappointment and despair deep into the minds of the wife and children. One of the most prolific causes of intense and continued anxiety, ending often in both physical and mental ruin, is the use of alcoholic or fermented and distilled drinks that takes directly from the earnings of labor in this country more than \$500,000,000 annually, and brings the most intense and protracted anguish to the minds of many thousands of innocent parties. In regard to this one influence, Dr. Brainerd, in discussing the report of Dr. Robertson, made the following statements: "Regarding alcohol it is difficult to obtain the figures. The statistics ordinarily obtainable were those from patients sent to the insane asylums. From these you could not find more than *one* case in *ten*. On getting the histories of the cases we find that alcohol as a direct cause does not play so important a factor as it does as an *indirect* cause. He had investigated some 90,000 cases, and found that the percentage attributable to alcohol was less than 8 per cent. His own experience in some four or five thousand cases satisfied him that the indirect

proportion with which alcohol should be credited was nearly 16 per cent.; and some even placed it as high as 25 per cent." It is thus seen that these very cautious inferences make the direct and indirect influence of alcoholic drinks the cause of 25 per cent. of all the cases of insanity in this country.

TYPICAL FORMS OF DISEASE MODIFIED BY CLIMATIC AND LOCAL CONDITIONS.

Apropos to the remarks of THE JOURNAL in its issues of April 13th and 20th, on the "Preferable Climate for Phthisis," brought out by the paper of DR. DENISON, it now extends its consideration of climate so as to include its modifying and typifying influences on diseases generally, and on some of the more prevalent diseases of given localities particularly. Much may be gained by a careful survey of the changing and varying types of diseases prevalent in our respective fields. A careful retrospective study of the various potencies which may have played a more or less important part in stamping prevailing diseases generally with their peculiar types, is productive of great good. We may look over the field of battle after the smoke and din have gone, and note with much clearer sight the relative position of the forces employed, than could have been done during the strife; and so it is with our struggles with disease. We may profit much by the study of past experiences.

Take, for illustration, typhoid fever as the disease, and take New England, Pennsylvania and Ohio for one part of the field, and Illinois, Iowa and Nebraska for the other part, the same observer transplanted from the former part of the field to the latter will be strongly impressed with the marked differences of type of the disease in question, as observed in different parts of the field. He sees it in one locality a *typical* disease; he sees it in another locality an *atypical* disease. Why the difference? There can be no doubt as to the identity of the disease in the two parts of the field; but the difference in type is striking and perplexing. We turn at once to climatic influences for a solution of the problem. In this there are many factors. Each plays its peculiar rôle in the typification of diseases. There can be no doubt about that. Impurities of atmosphere are many and dependent on a

multitude of circumstances. In this the nature and composition of the soil, its state, as to rest or disturbance, has much to do with the purity of the atmosphere in any given locality. In the eastern end of our field the soil abounds in good clay, sand and rock, and in the western end a deep, black vegetable loam prevails. This loamy soil is abundantly productive, and the great ease with which it can be brought under cultivation, makes agriculture on an extensive scale possible. Hence the area of soil undergoing the agitation incident to grain culture is comparatively very great. Our knowledge of the nature and character of malaria is as yet limited, but whatever it may be, we know that it thrives best on decomposing animal and vegetable matter; that it requires certain degrees of heat and moisture for its greatest activity. Hence we have in the western end of our field the conditions prevailing which most strongly conspire to impregnate the atmosphere with malaria.

In this, facts comport with theory. We have in this part of our field a *malarial climate*. This makes itself manifest in a multitude of ways. At times, and in certain localities, malarial diseases prevail to a large extent, at other times and in other localities it requires other disturbing influences to bring to the surface evidences of its activity.

Perhaps it may be a wound of inconsiderable gravity, but sufficient to make its shock felt throughout the fabric; perhaps it may be the disturbance incident to child-birth; or the commotion which obtains in acute rheumatism; or the much greater molecular disturbance which obtains in typhoid fever, the effect is largely the same. Sometimes a comparatively slight injury to an important joint, such as the hip, knee or ankle, the shoulder, elbow or wrist, the shock, though slight it may be, resulting from such violence may develop into symptoms of an alarming nature and embarrass the surgeon greatly. But when the malarial factor is once recognized and taken fairly in hand, the progress and history of the case to a successful issue is simple enough.

The puerperal woman may at any period of the lying-in state manifest symptoms of an alarming character; she may have had a severe chill, followed by high temperature, copious perspiration, great exhaustion, and all the symptoms usually attendant on puerperal fever. A prompt recogni-

tion of the malarial character of the complication, and the employment of appropriate therapy will dispel consternation and guide the patient to an early and safe recovery. On the other hand, a mistaken diagnosis will increase and intensify the complication.

A case of acute articular rheumatism may present a marked set of symptoms, but if carefully analyzed and interpreted, and the appropriate anti-malarial remedies employed, the complications disappear and the case proceeds to an easy and successful termination.

Typhoid fever occurs in a community, the symptoms are not regular, there are no typical cases, all of a mixed or masked character, all run an irregular course, yet all are of unmistakable typhoid origin, all manifest some of the regular symptoms of typhoid fever, none however have the full measure of typhoid characteristics, and none present more than one, or at most two, unmodified typhoid features.

Complications of rare and unusual character occur; one line of complications prevailing in one locality, and another set entirely different obtaining in another.

In a circumscribed district hæmorrhage from the intestinal tract may prevail to an alarming extent. Perhaps two out of five cases may present this fearful and largely fatal symptom. In another district, it may be at no very great distance from the former, inflammation and suppuration of the parotid gland may be the predominating complication, this untoward feature of the malady occurring in a large percentage of the cases, with the odds largely against the recovery of any case in which it occurs.

In still another district, perhaps not a score of miles distant from either of the former, still another complication of special significance occurs, with equal constancy, but with perhaps less prognostic fatality, in which the nerve centers are so impressed that aphasia and other manifestations of a similar character occur with marked regularity. These modifications, these differences, these varied complications, are undoubtedly the offspring of climatic influences, but just how much of a figure the malarial factor may play in the production of these phenomena, and to what extent their occurrence may be due to other and less demonstrable climatic conditions, is difficult of definite determination. The fact is

readily established, however, that malaria is the prevalent modifying influence in the class of cases cited. This can be done by the timely and judicious employment of our most reliable anti-malarial agent, quinine.

These facts are worthy of careful study and investigation. The study of climatology should engage the most earnest efforts of our schools and colleges throughout the country. A clearer understanding of the influences of climate in the production and modification of diseases would go far toward solving problems hitherto unexplained.

ALLEGATIONS OF HARSH TREATMENT OF THE INSANE.

During the last few years the reading public has been often shocked by reports of great cruelty and sometimes deaths from harsh treatment of the insane in public asylums for the care of that unfortunate class. One of the most recent of such reports has come from the Cook County Asylum for the pauper insane, in which an inmate named Burns is alleged to have died in consequence of the kicks and blows inflicted by two or three of the men employed as attendants. The post-mortem showed evidences of most extensive bruises, with fracture of one rib and the sternum. The primary judicial proceedings developed evidence that the Asylum is greatly overcrowded with patients and managed with a very inadequate number of attendants, many of whom, owing to the small wages paid and the repulsive nature of the work, are taken from the more rough and ignorant classes of society. While such conditions exist, it is unreasonable to expect that exhibitions of ill temper and inhuman violence will not often occur. No time should be lost in making such additional accommodations as will suitably provide for all the inmates; and no medical man should consent to take the superintendency of such an institution unless he is permitted to select and employ a sufficient number of intelligent and humane nurses or ward attendants to maintain order and reasonable discipline without exhibitions of ill-temper or the infliction of personal violence on the poor inmates.

EDITORIAL NOTES.

TIMES AND REGISTER.—We learn from *The Medical Register*, April 27, 1889, that a union has

been effected between *The Register*, *The Philadelphia Medical Times* and *The New York Dietetic Gazette*; and that on May 4th the united journals will appear under the title of *The Medical Times and Register*, with Dr. William F. Waugh, of *The Times*, as chief editor. Dr. John V. Shoemaker retires, on account of the pressure of other literary engagements, but the remaining writers hitherto engaged on the three, will continue their work for the combined journal.

OHIO STATE MEDICAL SOCIETY.—The forty-fourth annual meeting of this Society is to be held in Youngstown, Ohio, May 22d, 23d, and 24th, 1889. A full programme of work has been arranged, and railroads promised the usual reduction in fares, on the certificate plan. P. S. Connor, M.D., President, Geo. A. Collamore, M.D., Secretary, Toledo, Ohio.

THE STATE MEDICAL SOCIETY of Wisconsin will hold its next annual meeting in Milwaukee, commencing on the *first* Tuesday in June, 1889. For further information apply to J. T. Reeve, M.D., Appleton, Wis.

THE INDIANA STATE MEDICAL SOCIETY held its annual meeting in Indianapolis, May 1st and 2d, 1889. A good number of members were present. Dr. J. F. Hibberd, of Richmond, Indiana, as Chairman of a Committee, stated that there are 4,163 registered physicians in that State. Of this number 3,243 are regular physicians, of whom about 1,300 are members of the State Medical Society; 287 are classed as eclectic; 199 as homeopaths; 142 as physiomedical, and 192 unclassified. On the second day of the meeting the following were chosen as officers of the Society for the ensuing year: President, Dr. J. D. Hatch, of Lawrenceburg; Vice-President, Dr. S. T. Yount, of Lafayette; Secretary, Dr. E. S. Elder, of Indianapolis; Assistant Secretary, Dr. T. C. Kennedy, of Shelbyville; Treasurer, Dr. F. C. Ferguson, of Indianapolis; and Committee on Necrology, Dr. J. F. Hibberd, of Richmond.

THE NORTHAMPTON COUNTY (PA.) MEDICAL SOCIETY will hold its fortieth annual meeting in Easton, June 20, 1889, at which time a complimentary dinner is to be tendered to Dr. Traill Green, the founder of the Society, and one of the most meritorious members of the profession in the State.

SOCIETY PROCEEDINGS.

Medical and Chirurgical Faculty of
Maryland.

*Ninety-first Annual Session, held at the Hall of the
Faculty, Baltimore, Md., April 23, 24 and
25, 1889.*

DR. JOHN MORRIS, PRESIDENT, IN THE CHAIR.

DRS. G. L. TANEYHILL, ROBERT T. WILSON AND
WILLIAM B. CANFIELD, SECRETARIES.

TUESDAY, APRIL 23—FIRST DAY.

THE PRESIDENT'S ADDRESS.

After greeting the members, he said that the Faculty was now celebrating its ninety-first birthday, and that he had watched its career for nearly a half century, and was the only surviving member who had entered its gates by examination. He then addressed the members on the following subject:

THE PHYSIOLOGY AND PATHOGENESIS OF CRIME.
HOW FAR CAN MEDICAL MEN AID IN ITS
PREVENTION?

The teaching of the day appeared to be to make the physician a naturalist and a physicist. In studying these sciences the higher study should not be neglected—the study of society; the study of man, and his relations to his fellow-men, the advancement of the race through its physical cultivation. Millions of diseased men remain uncared for and the causes that have led to their degeneration are overlooked and unstudied. Physical culture is studied in the schools, but the character is not built up. We attempt to reform criminals, to rehabilitate them and ameliorate their condition. We should use prophylaxis. To prevent a man from becoming a criminal we must begin with him as a child. There is nothing practical in our moral and religious education. Even the sense of right and wrong is not clearly, effectively and practically taught. It is only the education that seeks to stimulate every noble purpose and capacity that can avail to form or change character, and this kind of education is not obtained in the school and the church. Every one cries out against immorality, but no steps are taken to create morality—to make morality a public sentiment; to make it a subject of national pride. Yet these are the prominent, the prevailing influences in Japan. There crimes of violence and outrage are scarcely known.

Where the law of heredity is recognized it is the duty of the medical man to forewarn parents, and to suggest the proper education and surroundings to render innocuous the taint of blood. This law of heredity obtains even more in moral than in physical traits, although the latter also, as we

know, can be transmitted. "Breeding back" would often render a happy change in our economy. "Begin with the man's grandfather if you wish to reform him." The family doctor has disappeared, but he must be brought back, to occupy a higher and a wider field. We are born with unalterable tendencies which are not always evil. The Jew and the Gypsy are examples of unalterable types. Psychology rarely enters into the education of a physician, and yet the questions of moral responsibility are associated with it. Ordinarily the physician treats the body alone, irrespective of the mental organization. He is but half a physician. The body yields to the mind, the mind to the body rarely. The weakness or total absence of certain powers of mind is rarely noted in children, and yet this observation is of the highest importance in shaping their future lives. The physician should be consulted in regard to the education of a family of children, and to do this he must have been trained by a long course of mental observation.

No man is born a criminal. We are not taught to value the truth. Perjury is the most common crime in our country, and yet it is rarely punished. The church and State have done little to regulate marriage, except the Roman Catholic church and the Church of England. Marriage should be regulated by law. Paupers and criminals should be prevented from marrying. The Legislature of Kentucky has a bill before it to regulate marriage. The tramp and malingerer should be stamped out; they need not exist. It is as harmful to bring insane children into the world as it is to drive them insane by bad usage. The habitual criminal, man or woman, should be deprived of the power to procreate.

In all our original research, let us not forget these questions. Let it be directed to the foundations of life; to the evolution and structure of character; to the evolution and building up a higher intellectual and moral constitution of the race; not to a childish search after pebbles and toys, of jackstraws in place of the true gold. In any and every event our work will go on—our profession will live as long as the ages endure. The more we advance in knowledge, the more the world will need us. As the astrologist, the alchemist, the barber of the Middle Ages, gave place to the pompous and pedantic oracle of the seventeenth and eighteenth centuries, with his latinity, his lancet and his squirt—the last like the spear of Telamon, which healed at one end the wound inflicted by the other; and as the oracle was followed by the man of the present time, with his ologies and marvelous nomenclature, his thousands of drugs, his hypodermic syringe and his microscope, seeking after the unseekable; so, in the future, this present man will be succeeded by a race of men of advanced thought, of truer convictions, of stronger culture, of higher and

broadier views; to the end that the State may be enlightened and improved, humanity benefited, and religion exalted.

WEDNESDAY, APRIL 24—SECOND DAY.

DR. WM. OSLER, of Philadelphia, delivered the *Annual Oration*. (See page 649.)

Section on Surgery.

DR. RANDOLPH WINSLOW, CHAIRMAN.

The chairman called attention to the subject of

SURGERY OF THE CENTRAL NERVOUS SYSTEM,

and dwelt especially on the importance of understanding thoroughly the general and topical anatomy of the brain, and then referred to the important results obtained by experiments on animals, by clinical observations, post-mortem examinations, and by electrical stimulation of the exposed human brain during the performance of surgical operations. The cortex and base are most accessible and amenable to surgical procedures. Tumors of the brain are of more frequent occurrence than general practitioners think. W. Hale White and Victor Horsley have done the best work here. Cranio-cerebral topography is a new and very important study and has been mainly used in the surgical treatment of epilepsy, brain abscesses. The study of

SURGERY OF THE SPINAL CORD

is of more recent date. Few cases have been reported.

In the same Section DR. OSCAR J. COSKERY reported a case of

TREPHINING FOR CEREBRAL ABSCESS,

with the result of removing the pus and giving motion to a paralyzed arm and leg, but the patient subsequently died.

DR. JOHN C. JAY then reported

A CASE OF ENTIRE EXSECTION OF THE ULNA WITH RESECTION OF THE HUMERUS AND RADIUS,

in a woman 49 years old. Complete ankylosis did not occur and the elbow remains movable to the extent of several inches, and thumb and two fingers can be used. The operation was fully justified by the excellent results.

Section on Practice of Medicine.

DR. WILLIAM B. CANFIELD, CHAIRMAN.

DR. CANFIELD took up the following subjects:

I. THE RELATION OF DUSTY OCCUPATIONS TO PULMONARY PHTHISIS.

He began by saying that the pulmonary diseases caused by the different kinds of dust had received a variety of names according to the character of dust inhaled, but collectively they were all covered by the name "pneumonocomiasis."

Ever since Koch's discovery of the tubercle bacillus, and the gradually improved classification of lung diseases, there seemed to be doubt whether these dust diseases were tuberculous or not. The dust inhaled by miners in badly ventilated mines gradually overcame the action of the ciliated epithelium and penetrated to the alveoli of the lung, whence they found their way into the subepithelial layer, where, unless rendered harmless or devoured by the greedy phagocytes, they set up a fibroid condition of the lung. Most writers agree that the fibroid condition is a barrier to the growth and multiplication of the bacillus.

He then related the case of a miner who had a fibrosis of the lungs, and in whose sputa bacilli were always found at every examination, and yet the man improved and is now well. His conclusions were:

1. Patient had no previous history of, or predisposition to, tuberculosis.
2. He contracted a disease with which tuberculosis is supposed to be very rarely found.
3. He had tubercle bacilli in abundance in his sputa.
4. He is now entirely well.

II. THE PRESENT ASPECT OF THE QUESTION AS TO THE ETIOLOGY OF PNEUMONIA.

Pneumonia results from something more than "catching cold." Sailors lead an exposed life and rarely have it. A large number of investigators have been looking for the specific organism. Talamon did some excellent work. Friedländer's pneumococcus was accepted for a time, but the investigations of Fränkel and Weichselbaum have shown Friedländer's organism to be only an accidental accompaniment of pneumonia. Good work has been done by Gamaléia, Sternberg, Lipari and others. He referred to the theory of phagocytosis in connection with this subject, and related his own experience in the bacteriological study of the organism. He then took up

III. THE MORE RECENT TREATMENT OF PULMONARY PHTHISIS,

and spoke of the failure of Bergeon's method. Treatment has been carried out by:

1. Internal administration of drugs or medicines.
2. Intrapulmonary injections.
3. Inhalations.
4. Climate. And cures occasionally occurred.
5. Spontaneously.
 1. The principal remedies recommended of late were creasote, tannin, calomel and morrhual. He had used creasote with some success.
 2. Intrapulmonary injections had been discarded.
 3. Inhalations had no lasting influence on the lung tissue. Creasote, hydrofluoric acid and hot air had all been used. Weigert claims to get some good effects from the latter.
 4. Climate, in early cases well selected, is the

best treatment. Many observers, particularly foreigners, gauge the improvement or the reverse by the diminution or increase of bacilli found. This hardly seemed to be the proper test. Patients often do well when their sputum is laden with bacilli. Cures may result spontaneously, as Vibert has shown in his statistics gathered from the Paris morgue. In 131 persons between 20 and 55, all of whom died violent or sudden deaths, in 17, or 68 per cent., evidences of cured consumption were even found in the lungs. These facts should be borne in mind by those reporting cures from the use of new remedies.

DR. W. S. FORWOOD, Darlington, Md., said that the "flint disease," as it was called in Hartford County, was very common and very fatal with the workmen in the quarries. The men all have this disease, which begins very insidiously and grows worse. It ends like consumption, but the beginning is very different. In reply to Drs. Randolph Winslow and A. K. Bond he said that no one escaped the disease after working in the quarries, and all were permanently injured, even if they gave up the occupation in a year.

DR. J. T. WRIGHTSON, of Newark, N. J., said that lung disease was very common among the hat-makers of his city, but he attributed it not so much to the dust as to drinking.

THURSDAY, APRIL 25—THIRD DAY.

Section on Obstetrics and Gynecology.

DR. T. A. ASHBY, CHAIRMAN.

The chairman remarked first on the growing tendency to abandon empirical methods and to employ more rational views of pathology and treatment. The study of abdominal surgery claims attention. Exploratory laparotomy is the only correct means to use in some cases. Laparotomy for pelvic abscess is a subject gradually gaining upon the professional mind. Primary laparotomy in tubal pregnancy has been brought into conspicuous prominence; but the greatest interest has been aroused in the use of

ELECTRICITY IN GYNECOLOGY.

He then discussed the various diseases for which electricity had been used, and then showed how much had been accomplished by it in a short time.

DR. L. E. NEALE then exhibited

A NEW OBSTETRICAL FORCEPS

which was a modification of Howard's modification of Tarnier's. He called it "Neale's Forceps." He claims superiority on the ground that it is all hard metal, and can be made thoroughly aseptic, has Simpson lock, blades are narrow, preventing rupture of perineum. It is made by Williams, of Baltimore.

DR. P. C. WILLIAMS praised it very highly.

He liked Tarnier's handles. In using it as ordinary forceps, he thought there was not force enough at the handle to manage it. It had many advantages which made it a superior instrument to the others.

Section on Materia Medica and Chemistry.

DR. T. BARTON BRUNE, CHAIRMAN, read a paper on

SUGAR TESTING, WITH SPECIAL REFERENCE TO "ALCAPTONURIA,"

in which he reviewed the various substances giving a sugar reaction, and the danger of trusting too much to one test alone.

DR. W. B. PLATT took up the subject of

SURGICAL THERAPEUTICS,

in which he considered all curative non-mechanical agencies employed in surgical cases, whether after accident, operation, or for surgical diseases. These he classified as anæsthetics, antisiphilitics and antiseptics. In the first class he discussed protoxide of nitrogen, chloride of methyl and cocaine. Under antisiphilitics were mentioned mercury inunction, hypodermic injections and gray oil. The antiseptics were carbolic acid, creolin and iodoform.

DR. WHITFIELD WINSEY then read a paper on

HYPNOTICS AND ANTIPYRETICS.

In the former class he reviewed what is now known of sulfonal, and drew the following conclusions:

1. It is a true hypnotic.
2. It is easy of administration, being without taste or odor.
3. It is safe, prompt and efficient, with objectionable after-effects.
4. No sulfonal habit contracted.

Under antipyretics he went over very thoroughly the literature of antipyrin, antifebrin and phenacetin.

DR. H. SALZER read a very exhaustive paper on

LAVAGE,

and gave the indications for its use in adults and children, and his experience with it.

In the discussion which followed, the remarks were confined to glycosuria and the sugar tests.

DR. A. K. BOND thought the testing for sugar was not so simple a method as it appeared. He thought the phenylhydrazin chloride test was the most satisfactory, but agreed with Dr. Brune that no one test should be used alone.

DR. GEORGE J. PRESTON thought it was important to know whether the amount of sugar increased or decreased.

DR. WILLIAM B. CANFIELD thought no test was reliable. He had succeeded with other tests where the phenylhydrazin chloride test had failed. He thought the use of the microscope was an ob-

jection to this test, as probably two-thirds of the medical graduates of the United States did not know how to use a microscope.

DR. J. C. HEMMETER was surprised that the saccharinmeter had not been mentioned. Salkowsky and Leube proved that it showed the presence of $\frac{1}{10}$ of 1 per cent.

DR. T. B. BRUNE, in closing, said he regretted to bring such a long discussion before the Society. The phenylhydrazin chloride test had not been long enough before the medical public to judge of it yet. Some other substance, as carbohydrater, may reduce these crystals.

Section on Sanitary Science.

DR. W. C. VAN BIBBER read a report on the subject of

QUARANTINE,

in which he discussed the Maryland Health and quarantine establishment, and referred particularly to yellow fever.

FRIDAY, APRIL 26—FOURTH DAY.

DR. F. T. MILES read a paper entitled: *A Case of Dilatation of the Stomach Dependent upon Contraction of the Pylorus* in which tetany of a typical character occurred, speedily ending in death. He could find nothing in the vomited matter to account for it.

DR. J. W. CHAMBERS submitted a paper on *Cystic Tumor of the Lower Jaw*.

DR. GEO. J. PRESTON reported a case of *Tumor of the Cerebellum* pressing on the middle lobe.

DR. J. D. BLAKE, in referring to Dr. Welch's paper, asked how the poison could be transmitted by the nerves alone? If injection into the blood does not kill, but makes the animal proof against future attacks, why not inject the substance directly into the blood of man to prevent hydrophobia?

DR. W. C. VAN BIBBER said if the temperature stated would kill the organism of rabies, this should give a valuable idea on the treatment.

DR. WM. H. WELCH remarked in conclusion that many facts about rabies were known which could not be explained. It was not understood how the virus was transmitted along the nerves, but the fact remains; and still further, this did not seem to disturb the function of the nerve. It might extend along the lymph vessels of the nerves; we know little of the composition of the lymph. He did not mean to be understood as saying that the virus did not extend through the blood lymphatics, but that we have no evidence of this. In reply to Dr. Van Bibber, he said that the method of cauterization is a good one, but it does not prevent rabies. The virus must penetrate into the nerve to be transmitted by it, and the chance of piercing a nerve in the skin by puncture is very small.

Section on Psychology and Medical Jurisprudence.

DR. RICHARD GUNDRY, CHAIRMAN.

THE CHAIRMAN read a paper on the

RELATION OF THE PHYSICIAN TO THE INSANE, in which he spoke particularly of the frequency of monomania, and of the difficulties of recognizing true insanity by the unskilled, as a person may be entirely sane on many subjects and insane only on a few. A person totally insane has no recollection of a deed committed, while a person partly insane may remember the past partly.

SATURDAY, APRIL 27—FIFTH DAY.

Section on Microscopy, Micro-Chemistry and Spectral Analysis.

DR. CHRISTOPHER JOHNSTON, SR., CHAIRMAN.

THE CHAIRMAN read a report on: I. *The Application of Spectroscopy to the Study of the Blood*. II. *The American Objective as Compared with the German*.

Section on Ophthalmology, Otology and Laryngology.

DR. H. A. MCSHERRY read a paper on *Curability of Laryngeal Phthisis*; and DR. A. FRIEDENWALD one on *Distorted Equilibrium of the Muscles of the Eye in the Causation of Nervous Diseases*.

Volunteer papers were then read by DR. S. J. FORT on *Aphasia, due to Shock of Severe Consecutive Epileptic Spasms*; by DR. JOHN C. HEMMETER on *Recent Investigations on the Physiological Activity of Alcohol*, which was the result of three years' carefully conducted work in the Biological Laboratory of Johns Hopkins University; by DR. A. K. BOND on *Aneurism of the Abdominal Aorta Bursting into the Pleural Cavity*; and one by DR. GEORGE H. ROHÉ on *A Painless and Efficient Method of Extirpating Vascular and Pigmented Nævi*, with exhibition of photographs.

The following were elected for 1889-90:

President—Dr. A. Friedenwald.

Vice-Presidents—Drs. T. A. Ashby and Chas. G. W. Margill.

Recording Secretary—Dr. G. Lane Taneyhill.

Assistant Secretary—Dr. Robert T. Wilson.

Corresponding Secretary—Dr. Joseph T. Smith.

Reporting Secretary—Dr. Wm. B. Canfield.

Treasurer—Dr. W. F. A. Kemp.

Gynecological Society of Boston.

200th Regular Meeting, March 14, 1889.

THE PRESIDENT, W. SYMINGTON BROWN, M.D.,
IN THE CHAIR.

PATHOLOGICAL SPECIMENS.

DR. F. L. BURT exhibited a *fibroid of the uterus* which he had removed from an unmarried woman about 30 years old. It filled the vagina

and was attached by a small pedicle near the internal os uteri. The tumor, the size of an orange, was removed with considerable difficulty from its attachment, and when free it could be removed from the vagina only by the aid of the fingers in the rectum. The hæmorrhage, which had been considerable, gave no more trouble.

An interesting paper was read by AUGUSTUS P. CLARKE, M.D., entitled

FARADISM IN THE PRACTICE OF GYNÆCOLOGY.

In these days of brilliant theories and magnificent possibilities, he said, much is claimed in regard to the value of the galvanic current in the treatment of certain diseases of women. Results far in advance of anything that a generation ago the most enthusiastic advocates had even hoped for, have been achieved by Apostoli and his followers. The elaboration of this system of electro-therapeutics has been accomplished only by the expenditure of a vast deal of money and thought. Instruments and appliances the most ingenious, have been devised to meet the various phases and indications of what may be termed a normal departure, suggesting the adoption of remedial measures. The work in this field has many attractions, and is capable of satisfying the longings of natures the most ambitious, and of yielding a feeling of complacency, that can only be rivaled or reached by the eclat, that is sure to follow successful cases of laparotomy and ovariectomy. Indeed, the definition of the term electricity or electro-therapeutics of late in some quarters has become almost identical with galvanism. The display by the development of such special appliances are led to further inquiries in regard to the treatment of cases of a gynæcological class by the application of the faradic current. It is to be noted that the results obtained by the employment of this form of electricity have been most gratifying and give promise of the attainment of results which, without the employment of this current, could not be secured. Apostoli's method of treatment of chronic metritis and endometritis comprises an intrauterine chemical galvano-cauterization to be carried out in a strictly antiseptic manner. The sittings, though short, must be frequent if they are to be successful. The application of this method necessitates the use of special rooms and conveniences, which only a few among the larger operators are likely to have. Any departure from the prescribed plan is almost certain to be attended with much danger. When we consider the necessity of repeating frequently the sittings before we can even hope for success, we are forced to conclude that this plan of treatment will never become very popular. Operators, who have special conveniences and who have reason to hope for successful issue of the cases, will always prefer treatment by laparotomy or other surgical methods in which

the lives of patients in most instances are to be jeopardized but once, than repeatedly to incur risks by the method of chemical galvano-cauterization. In the employment of the faradic current we act upon the superficial blood-vessels, we modify the nutrition of the parts, we hasten absorption of extraneous matter. All this can be done without incurring that extreme hazard which usually accompanies methods by galvanization.

The faradic current has a markedly sedative effect upon the parts, and when judiciously and intelligently applied the patient often feels a sense of relief, and will return for further help. Even in cases in which marked inflammatory processes are present, the faradic current may be resorted to with much benefit. In a paper presented to the Association of Obstetricians and Gynæcologists, Washington, D. C., September, 1888, I reported several cases of salpingitis, in which the treatment supplemented by faradization was productive of much benefit. Cases in which the abdominal walls were soft and unusually relaxed from want of tone, or in which there was undue distension induced by various lesions were greatly relieved by the employment of the faradic current. The following cases are appended to show the more favorable results of the treatment.

Case 1.—Mrs. K., æt. 38 years, mother of one child, 13 years old, notified me July, 1888, that she expected to be confined in September following. I saw the patient July 21, and made careful examination, and found that she was not pregnant. Her menses had appeared at irregular intervals, but the distension of the abdomen was so great that she supposed herself pregnant, and had made elaborate preparation for confinement. The bowels were regular, she had fair appetite, and the urine appeared normal. There was some pain and tenderness over each ovary. The circumference of the abdomen was greater than normal and the patient fancied she felt foetal movement. The uterus was soft and relaxed and was anteverted, but not to such degree as to cause vesical disturbance. I began with the use of the faradic current with slow interruptions over the abdomen and the cervix, while over the ovaries on the outside frequent interruptions of the current were employed. Occasionally an intra-uterine electrode was employed while the other pole (usually the negative) was connected with the wire brush. The patient quickly improved under this method of treatment. Abdominal distension subsided, and the pain and discomfort in the ovaries disappeared. The sittings were continued at intervals of three days, and each occupied from five to ten minutes, and covered a period from August 14, to November 17, 1888, since which date she has been in good health.

Case 2.—Mrs. O., mother of three children, the

oldest 12 years, the youngest 4 years. This patient had been an invalid for several years. There had been an old perineal laceration though no prolapse nor any vesical disturbance. The cervix was thickened and indurated. There was no leucorrhœal discharge nor any history of an acute inflammatory process. The patient had worn several kinds of pessaries, but said that she had never experienced any special benefit from their use. The principal trouble complained of when she came under my care, was pain in the back and left ovarian region, and at irregular intervals attacks of severe pain in the head, attended with symptoms which showed that hysteria was an important element in the disease. As this patient had been under the usual routine of several able practitioners, I advised discontinuance of the use of all supporters and other means of treatment heretofore received, and began with employment of the faradic current. The treatment was commenced in the early part of August and was continued at intervals of three and four times a week; each application of the current lasting eight minutes. Over the more painful points the current with frequent interruptions was used. Along the muscles of the back and areas of great sensitiveness the current with slower interruption was selected. The negative pole with an intra-uterine electrode was applied. After the third application of the current the patient showed signs of improvement. The treatment was persevered in regularly for two months. After that the séances were continued at longer intervals. The treatment was supplemented with an aloetic purge and followed by the daily use of gentle aperients. The patient, though not fully restored to health, so far recovered as to be able to attend to her domestic affairs, and to go out and enjoy many of the comforts and pleasures of life. It is highly probable that eventually an operation for the restoration of the perineum will have to be undertaken.

Case 3.—Mrs. S., æt. 26 years, married five years, miscarried after the third month of pregnancy. The placenta was retained upwards of sixty days. When I was called there was flowing and a fœtid discharge. I succeeded in effecting an entire removal of the placenta. The patient after that rapidly improved, but was anæmic, and the tissues were soft and relaxed. After four months the patient returned to me complaining of vesical disturbances. Vaginal examination showed that the uterus was retroflexed, and that there was a well defined cystocele. The uterus was restored and the patient was directed to urinate at short intervals, and to avoid if possible the occurrence of over-distension of the bladder. After the lapse of six months, there being still considerable vesical disturbance, faradization was begun. Slow interruptions of the current were employed in the cul-de-sac on

each side and over the abdomen. The séances were made every third day for four weeks and then at intervals of once a week. After the second month the patient considered herself to be cured. Recent examination showed that, though the patient had received no treatment for nearly six months, the cystocele had not returned, and the retroflexion was of no consequence. The patient is now strong and in good health.

Case 4.—Mrs. R., aged 38 years, mother of two children, the youngest of whom was 15 years. After the last confinement she suffered very much from catarrhal endocervicitis, but the menses have appeared regularly. Vaginal examination showed that there had been a multiple laceration of the cervix, but the cicatrization was fully established. The cervical canal was preternaturally sensitive. The perineum had been lacerated, but nature had partially restored the rent. The uterus was retroverted. The principal trouble complained of when the patient came under my care eight months ago was pain in the ovaries. These could be distinctly felt and were not displaced. There was pain also in the back, from the lower dorsal vertebræ to the coccyx. The tendon reflex was markedly increased. The patient suffered from frequent attacks of "blinding headache." The urine was heavily loaded with urates. Under ether I curetted thoroughly the cervical canal. The uterus, after being restored, was kept in place by vaginal tampons. Butcher's meat was interdicted, and the bowels were kept open by gentle aperients. The patient improved under the treatment. After the lapse of three months slow interruptions of the faradic current were tried every third day for five weeks, and for the next four weeks once in every four days. Subsequently once in two weeks. The treatment by faradization occupied upwards of four months, and its good effect was shown by the disappearance of the increased tendon reflex and the return of strength and appetite. All pain and tenderness vanished, and the local lesions now give no trouble whatever.

Case 5.—Mrs. S., aged 38 years, mother of one child 4 years old. The patient recovered well from confinement and was in good health until January, 1888, when she sustained injuries from being thrown from a carriage. She suffered much at the time, was confined to bed. There was severe pain in lower part of back and in the bladder. She suffered more or less in micturition. There was no uterine displacement, but a sharp pain and soreness in the right ovary was complained of. After two months of rest and treatment the pain and soreness disappeared, except that in the ovary. The ovary of that side must have been affected by the shock and concussion sustained. In March following, faradism was tried. The positive pole was applied over the abdomen, and more particularly in the right in-

guinal region and in the right cul-de-sac. The other pole was applied along the lumbar and sacral portions of the spine. The wire brush on the outside was also used. The patient showed improvement after the third séance. The sittings were continued at intervals of two and three days until April 15th. Since then no further trouble has been experienced from the ovaritis, and the parts have resumed their normal functions.

Case 6.—Mrs. A., æt. 41 years, mother of three children, the youngest of whom was 9 years old. For the past five years the patient had had several attacks of rheumatism, necessitating at the time of each attack confinement to bed. When I was called she was recovering from one of these attacks which had continued from Sept. 10th to Oct. 24th. There was swelling of both knees and ankle joints, but the greatest amount of suffering appeared to be centered in the pelvic organs, especially in the uterus and its adnexa. Mineral waters and saline laxatives were employed. The use of meats and nitrogenous food was discontinued, and milk and light articles of diet were prescribed. The patient rapidly improved under the change of treatment and on Nov. 1st was free from the rheumatic affection, except weakness and discomfort in the back and genito-urinary organs. The patient was unable to walk without the aid of a cane or crutches. There was uterine dyskinesia, though no marked flexion of that organ could be made out. There was a sensible diminution of the tendon reflex and almost an entire absence of the ankle clonus. At this time treatment by faradization was begun, and continued until Dec. 12th, when the pain was overcome and the patient able to walk without artificial help. The reflexes have returned to their normal condition. The current with slow interruption was applied every second day.

Case 7.—Mrs. L., æt. 22 years, while walking on a country road during the evening of Jan. 15, 1888, sustained a fall over an embankment. At the time of the accident uterine hæmorrhage occurred. The patient is said to have complained bitterly of pain in the right hip and back. She was under treatment for six weeks, at the end of which time she had so far recovered as to be able to return to her home. The patient came under my care on the 10th of the following May. Vaginal examination showed that there was a marked ante flexion. There was vesical disturbance and considerable difficulty experienced in walking or in attempting to make any considerable exertion. A Hodge pessary gave only partial relief, but was worn until August 3d, when I removed it permanently, and began with faradic current with slow interruptions. Each séance lasted ten minutes and was repeated every third and fourth day. After the sixth application the uterine tissue appeared firmer and the organ itself on being restored retained its position much

longer than before. The treatment was persevered in until October 8th, when the patient regarded herself as well as usual. Vaginal examination showed that the uterine flexion existed in a minor degree only.

In reviewing the histories and symptoms of these cases we find inflammation attended with more or less pain, and some form of neurosis was a prominent feature, and that the application of the faradic current was productive of much benefit. In Case 1, the current with slow interruptions had the effect of stimulating the relaxed muscular tissues, and of giving tone and vigor to the parts. In Case 2, the pain and reflex symptoms were relieved, and the strength and health improved, and should an operation for the restoration of the perineum be deemed advisable, the patient will be in much better condition to insure recovery. Case 3 shows the beneficial effects of the current with slow interruptions. A cystocele induced by overdistension of the bladder in a subject of weakened and relaxed muscular tissue was at length fully overcome by prolonged application of the current. Case 4 shows also benefit derived from the same current in controlling the tendon reflex and nervous excitability. Case 5 illustrates the therapeutical advantage of faradism when the wire brush is used. In the treatment of inflammation supervening shock and concussion of the ovary. Case 6 further shows the help to be derived from continued application of the faradic current in restoring reflexes to the normal condition and in exciting healthy action in the genito-urinary organs. The last case in some respects, like Case 3, exemplifies the tonic effect that may be obtained by the employment of the same current on relaxed uterine tissues.

I am in possession of notes and records of some thirty other gynecological cases in which faradization was resorted to with favorable results. In twelve of these the application was made to overcome pain and nervous disturbance arising from various lesions requiring operative interference, viz.: six for pyo-salpinx and salpingitis, four for lacerations of the perineum and of the cervix, one for uterine polypus and one for urethral vascular growths; and in nine to overcome pain and nervous phenomena due to functional disturbance, viz.: three for subinvolution, four for leucorrhœal and gonorrhœal pain, one for neuralgia of the ovary, and one menorrhagia. In two the application was made on account of amenorrhœa, in four for cystitis, and in three for hysteria and loss of power in arm and leg. These cases I report not with the view of establishing a claim for originality in treatment or for the purpose of setting aside other well-tried and settled methods, but in recognition of the fact that we have in this form of electricity for properly selected cases, after other means have failed, an agent capable of yielding most gratifying results.

DR. W. G. WHEELER said that he was glad to see a return to faradization. A good degree of success had been attained by Dr. Cutter by his method of treatment. He had in one case used Cutter's battery in treating a large tumor reaching above the umbilicus. The shock produced is profound, and it is necessary to etherize the patient. One needle was introduced through the rectum and the other through the abdominal wall. The current passed for seven minutes. An abscess was produced, which discharged for several months. The operation was performed a year and a half ago, and the tumor is now quite small and the sinus is closed.

DR. A. L. NORRIS has found better results from the use of the interrupted current. For the last eleven years he has used a battery made by Kidder, of New York, on a large number of cases with success. He has had good results in the treatment of amenorrhœa by faradization. For this, one pole is usually placed on the nape of the neck and the wire brush is applied over the loins, but sometimes he uses an intrantrine electrode.

DR. G. W. JONES: I think that Dr. Clarke should be complimented on the good results he has obtained from faradization. If we could all get such results we would be highly gratified, and not without reason; for the remedy is at once so simple and easy of application. For my part, however, I have not been able to obtain such encouragement. I have been using faradism for more than sixteen years in just such cases as Dr. Clarke has spoken of and, although I have sometimes thought improvement resulted, there was not such a decided benefit as to make me feel hopeful of very brilliant success. I say this of the faradic current when used exclusively. I have no doubt but that a judicious use of the faradic current may be of some benefit in many cases of leucorrhœa and simple metritis and ovaritis and neuralgia of the uterus and ovaries. Also in some cases of hysteria due to pain in the locality of the generative organs, it might have a moral if not a physical influence; but when the various disturbances of the female reproductive system are due to morbid tissue changes in those organs, I believe that faradism will have little if any influence on those morbid conditions. In such cases galvanism is going to do the most valuable service. We do not want to stimulate cell-growth, but rather retard or destroy such cell proliferation, and in the galvanic current we have an agent that will do that in the best manner, if it is used in a careful way. For all ordinary purposes, an apparatus consisting of 24 to 36 cells of McIntosh or Wait & Bartlett make will be sufficient to do the work of a general practitioner.

One of the greatest drawbacks to the use of galvanism to my mind, is the high cost of a good galvanometer to measure the current used. A

reliable instrument costs so much that few general practitioners are willing to afford the outlay when they so seldom use it, and I believe if we are to use an agent so potent for good or evil, that the dose administered should be as accurately measured as strichnine or morphine. If we expect so get exact results from our practice, we ought to know exactly how those results are obtained in order to have them of practical value.

DR. F. L. BURT: There seems to be no doubt that all are not equally successful in their results from the use of electricity. The enthusiast, who thinks it the only agent of good, is no doubt over sanguine and probably reports too favorably. He who decries it, on the other hand, has doubtless not taken the trouble to investigate properly. I am not so enthusiastic as to use this agent to the utter exclusion and denial of everything else, but I do know that it is of value and I have frequently been gratified at my results. Failure is very frequently due to a lack of knowledge in the application on the part of the physician, and a very frequent cause of failure is due to the use of poor batteries. A good battery is a necessity. Many of those on the market are good toys, but are almost useless in the treatment of gynecological cases. Two coils, coarse and fine wire, with a slow and a rapid vibrator, are necessary. I have used the faradic current with much satisfaction as an external application for its soothing effects, to ease pain, to stimulate muscles to contract, to test reactions in certain nervous affections, to increase peristaltic action, etc. In gynecological cases it has been of great service in some cases of amenorrhœa, to cause more regular menstruation, to ease menstrual pains and to relieve general pelvic pain. In cases of relaxed tissues or prolapse of the pelvic organs, there is a slow but beneficial result. The method of application and kind of electrode used to have much to do with the success in any given case. The reader has said very little about the method of application, but although it is quite important perhaps the profession is sufficiently informed in respect to it.

In the early part of his paper the reader gave me the impression that he laid a great stress on faradism and little if any on galvanism. Faradism has been used more commonly in the past, and I think with better results, but this could only have been because there was less knowledge of the use of galvanism. This is not so to-day. Without speaking at all disparagingly of either variety, I think that no one, who has thoroughly tried both kinds, will hesitate for a moment to give the preference to galvanism as the most generally useful electrical current. There is no longer doubt of its value in treating fibroid tumors. In some cases the results are excellent, yet it is equally true that there are cases which cannot be benefited by its use, and surgery must

come in for a certain number of cases. The symptoms are usually relieved or cured, discharges are lessened or entirely stopped and hemorrhage is checked. Galvanism will stop hemorrhage which is due to the presence of a fibroid or other intra-uterine causes, but is of no use when due to pelvic troubles external to the uterus. There is a class of cases of fibroid associated with diseased tubes or displaced and adherent ovaries, which is not benefited by electricity. These need surgery. I reported a typical case of this kind in the *Boston Medical and Surgical Journal* of January 24, 1889. Inflammatory pelvic deposits are absorbed by the use of galvanism. On the other hand, a point of considerable importance which I have mentioned before, the cases, diagnosed as pelvic cellulitis and which are frequently pyo-salpinx, are treated by galvanism and not benefited. This is due, according to my experience, to the fact of the presence of pus. In other words, pyo-salpinx or pelvic abscess is not relieved by galvanism, and this fact may aid in the diagnosis of the case. I have reported a typical case of each kind, for which see same reference as above. In the treatment of the disorders of menstruation and of diseases of the endometrium, I have thus far had decidedly beneficial results. Some cases in which there is more or less constant pain in the region of the ovaries in which the diagnosis varies, have been cured by the use of galvanism. There are also many conditions in which galvanism is useful, which I will not take your time to speak about, and still others which I am as yet investigating and hope to make a report in the future. Electricity, galvanism especially, should not be used by persons who are ignorant of it as a therapeutic agent, and the physician who is to employ it should be well versed in respect to its actions, and should know thoroughly the construction of the machine which he is about to employ.

DR. W. S. BROWN said that the cases detailed by the reader were very interesting, and of practical value. He believed that the primary faradic current exerted a remarkably soothing influence on excitable patients, under which they sometimes fell asleep during its administration. As he had several times related to this society, he was present when Dr. E. Cutter (now of New York) made his first attempt at electrolysis in Melrose, Mass. Dr. Kimball, of Lowell, also assisted, but, on account of the needles used being too slim, we did not succeed in penetrating the fibroid tumor. He was still in doubt whether the success in subsequent operations was due to electrolysis or to shock. Like all similar operations, it is not free from danger; and, in many respects, differs from Apostoli's.

DR. A. P. CLARKE: In closing the discussion the speaker said that he should offer only a few remarks. In the first place he would state that

he did not wish to be understood as holding to the view that the faradic can be substituted for the galvanic current. It is true, he said, that he had referred to the achievements of Apostoli and his followers, but that treatment comprises chemical galvano-cauterization. In order to insure success when adopting Apostoli's method, instruments of peculiar construction must be employed, and their application must always be made under the strictest antiseptic precautions. For this reason he believed that method of treating certain morbid lesions would never be popular, but other methods would be resorted to to accomplish the same results. The cases that are benefited by faradism are often radically different from those that may be benefited by galvanism, the former can be treated with comfort and safety to the patient and with satisfaction to the physician. The report of the 37 cases as given in his paper, as well as of those that he had already published, the speaker remarked, attest in some measure the benefits that may be secured by faradism. Something has been said in regard to the employment of the faradic and the galvanic current in the same case; the moral effect of such treatment may occasionally be of benefit, but the nature of lesions requiring the use of the galvanic and faradic current often being so different, he very much doubted whether, in the majority of cases, any permanent improvement resulted by their admixture. The speaker made mention of the helpful effects of the faradic current with slow interruptions in cases of weakened and relaxed muscular tissue; he referred particularly to Case No. 3 in the paper, in which a cystocele induced by overdistension of the bladder was cured by prolonged applications of that current. For overcoming pain and nervous excitability, the faradic current with frequent interruption was employed. He also referred to the results mentioned in the discussion by Dr. Burt, that were obtained by a fine and by a coarse coil of wire in his battery. The distinguishing features of these respective currents are important considerations. By keeping this principle in view the operator will often be successful with his cases; by neglect, however, utter failure may result. Reference has been made to Dr. E. Cutter's method of electrolysis, though a consideration of that method of operating is hardly germane to the subject now before the Society, the speaker would venture to remark that he had been favored with an opportunity of seeing some of the earlier cases of fibroids treated by that distinguished operator. He believed that Dr. Cutter should have the honor of being the originator of the treatment of uterine fibroids by electrolysis, and that he is deserving of great credit for the good work he so early accomplished.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

New York Academy of Medicine—Dr. E. F. Brush read a Paper on the Relationship Existing between Human and Bovine Tuberculosis—Discussed by Dr. H. M. Biggs, Dr. Forrest, Dr. Grandin and Dr. Loomis—Signs of the Moribund Condition, by Dr. John Shrady, etc.

At a recent meeting of the Academy of Medicine Dr. E. F. Brush, who for some time past has been making a special study of this subject, read a paper on *The Relationship Existing between Human and Bovine Tuberculosis*, in which he advocated the doctrine that tuberculosis in man is derived directly from the bovine species, and claimed that if domestic cattle could be done away with, tuberculosis would in the course of a few years become extinct, since while it has been conclusively demonstrated that the disease can be transmitted by the cow to her offspring, there is no proof that such transmission ever takes place in the human subject.

Phthisis, he said, was not, as many supposed, the result of civilization, since barbarous and uncivilized races were afflicted by it as severely as many of the most advanced civilized peoples. Neither geographical position or climatic conditions were a factor in its distribution, although every part of the globe, with the exception of a few isolated areas, was a habitat of the disease. After several years of close study of the affection, including a consideration of all available statistics and the habits of the people where it prevails, he said he had arrived at the conclusion that the only constantly associated factor is found in the inbred bovine species. If a community was closely associated with inbred dairy cattle, tuberculosis prevailed there, and this position he believed susceptible of proof.

After referring successively to statistics relating to phthisis among the Hottentots of Africa and the Kirghises of the steppes of Russia, and in Denmark, Iceland, the island of St. Michael in the Atlantic Ocean, Greenland, South America, Australia, New Zealand, the Highlands of Scotland, North Wales, the Hebrides, Switzerland, Madagascar, Algiers and Greece, he stated that in studying the relations, as regards tuberculosis, between the human and bovine races, religion was found to play a considerable part. Thus, in India, with the Mohammedan, Brahmin and Buddhist religions, there was undoubtedly an absence of phthisis before the English occupation. Up to that time the only cow the inhabitants had was the small Hindu variety, not related to our dairy cow, and it was regarded as an object of veneration; while the milk used in the country was de-

rived from the buffalo. All the Buddhists and many of the Brahmin castes abstained from the use of meat in any form. There was, however, a constant change taking place in a country like India. Prejudices were gradually dying out, and many of the people had undoubtedly adopted the habits of their conquerors. The English dairy cow was slowly but surely finding her way into India; though the Buddhists and Brahmins would, of course, be the last to accept the cow as a food producer.

In considering the statistics of Europe he said it would be found that the prevalence of phthisis is regulated by the ratio of the bovine to the human race. Thus, in Ireland, where the cattle about equaled the human population in number, and in Denmark, with about the same ratio of cattle to inhabitants, the disease was about equally prevalent. In Portugal, where there are six inhabitants to one bovine animal, phthisis attracted so little attention that but few notices relating to the disease in that country could be found. Comparative immunity from the disease, corresponding with the small number of cattle, was also met with in many parts of Italy and Egypt. From the statistics that he produced Dr. Brush thought there could be little doubt that the inbred species of the bovine race is the prime etiological factor of tuberculosis in the human race. They not only fostered the germ and prevented its extinction, but sowed it in the human race, continually and abundantly. Without their aid the germ would perish, for of all germs known, none had so hard a struggle for existence in man as the bacillus of tubercle; as was shown by the fact that out of the immense number of individuals who were exposed to its infection, so comparatively few contracted the disease. After diligent search he had failed to find a single well authenticated case on record of a human foetus at term showing evidence of tuberculosis; and the cow was the only known animal that thus transmitted tuberculosis to her offspring.

In concluding his paper Dr. Brush said: Man cannot generate new forms, but he can so control and interfere with nature's processes as to modify the original design. Inbred cattle are selected, sheltered and pampered, so that they would be unable to withstand the rigorous conditions of the wild state. They propagate earlier, are larger milkers, and are more efficient beef-producers, while their meat is more delicate and tender than that of the wild animal. All this is achieved by man at the expense of his own health.

In the discussion of the paper Dr. H. M. Biggs, of the Carnegie Laboratory, said that he could not but dissent very strongly from the conclusions reached by Dr. Brush. It was well known how unreliable statistics were. He believed that the statistics given in the paper were not strictly true; but even if they were true, he did not think they would prove the correctness of Dr. Brush's posi-

tion, for the reason that they left out of consideration all the other factors concerned in the production of tuberculosis. Having criticised some of the statements made in the paper in regard to the prevalence of phthisis in some of the countries and places mentioned, he stated that in Chili the disease had of late years become very common, although there had been no marked increase in the number of inbred cattle to account for this. Again, in the Sandwich Islands the population was dying off from phthisis; but this was not because of the presence of inbred cattle, but was due to the spread of the infection by white settlers. The same was true of the American Indians. They did not possess many inbred cattle; yet phthisis was very fatal among them.

Dr. Brush, he said, had left entirely out of account the influence of age, altitude and occupation, which had been shown to be very important etiological factors. If tuberculosis was often conveyed by means of milk the disease ought to be much more common among young children, who lived almost entirely upon this food, than among any other class of individuals; while as a matter of fact it was quite rare among this class. The facts appeared to show that phthisis is most prevalent among the highly civilized nations and among the native populations of uncivilized countries, which are brought into more or less constant contact with foreigners from civilized countries. It seemed to him that Dr. Brush had started out with the preconceived idea that phthisis is derived from the bovine species, and had endeavored to make all the facts he met with in connection with the disease subservient to this preconceived notion. The only observations which carried out this idea were based on statistics which, as he had said, he believed to be unreliable, and which would only be of value if they were collected with the greatest possible care, and with all the other conditions affecting the production of phthisis also taken into consideration.

In all civilized countries there are to be met with these other elements (and particularly that of occupation), which enter into the causation of the disease. Confinement in close, ill-ventilated apartments had a most pronounced effect upon males and females alike. More than this, the theory propounded in the paper was entirely inadequate to account for the marked prevalence of phthisis among armies and the inmates of prisons. Again, other things being equal, the disease was found to prevail in proportion to the density of the population.

We could not but regard Dr. Brush's conclusions as unfortunate, especially if they should be accepted, since they would have the effect of diverting attention from the most important mode of origin of phthisis, viz: transmission from the human subject. If the disease were derived from

animals it could only be through the avenue of the alimentary canal; and it was a well-established fact that the number of cases in which the infection enters the system through the alimentary canal is exceedingly small. In the case of animals fed on tuberculous matter the resulting tuberculous disease, when such occurred, was found to be located in the alimentary canal, not the lungs; and there was every reason to believe that the same would be true in the case of the human subject. In tuberculous animals, moreover, the milk was not infected with the bacillus unless the mammary glands are implicated in the tuberculous disease.

It seemed to him ill-advised to look for the cause of the trouble in this unlikely source (from animals), when there were so many ready ways by which the human system might become infected with tuberculosis. One of the most prominent of these was undoubtedly the sputum of tuberculous patients. The sputa of all such individuals abounded in tubercle bacilli, and when it was remembered how large was the quantity of the expectoration of consumptives and for how long a time the disease often lasted, it could well be appreciated what a source of danger to others this constituted. The sputum was apt to be scattered all around, and on its becoming dry the bacilli it contained often floated about with the dust in the air. The bacillus was the universally recognized special cause of tuberculosis, and it might thus be seen how readily it could be inhaled in this way, and so brought into direct contact with the lungs, which are the ordinary seat of the disease. Although he felt convinced that a much larger number of cases of phthisis really originated from animals than was generally supposed, this class, there was every reason to suppose, constituted but a small number of all the causes of the disease.

Dr. Forrest said that in certain sections of the Southern States with which he was familiar phthisis was almost wholly unknown among the whites, but was quite common among the blacks. Yet far more fresh beef and milk were consumed by the white population than by the negroes, who lived principally upon corn and pork. It was also a fact that a very fine stock of cattle was now raised in these same districts. He could not see how, therefore, this condition of affairs could be reconciled with the theory of Dr. Brush.

Dr. Grandin said that a little more than a year ago Dr. M. D. Blain had stated in a paper read before the Section of Public Health of the Academy that 2 per cent. of all cattle killed in the New York abattoirs and 21 per cent. of all the milch cows in the country were affected with tuberculosis.

The President, Dr. Loomis, said it seemed to him that the position taken by Dr. Brush was too narrow a one, and that any one who assumed that phthisis is due to one cause alone was beg-

ging the question. It was a disease that had many causes, and the bacillus which constituted its special etiological agent would not give rise to it unless it met with conditions which favored its development. Among the conditions to be taken into consideration were climate, hygienic surroundings, heredity and soil, and a long list of causes must be in operation before the bacillus was able to do its specific work.

In closing the discussion Dr. Brush said he thought that his position had been somewhat misunderstood. He did not wish to imply that the disease was derived alone from the cow. All that he pretended to claim was, that wherever in-bred cattle existed, there we found phthisis also. It needed no proof to show that but a small proportion of individuals who were exposed to the infection contracted the disease, since, although the number of deaths from phthisis was certainly very great, it would be infinitely larger than it is if this were the case. In addition to the bacillus, there must be present the conditions favorable to its development, as Dr. Loomis had stated.

But, at the same time, he believed that the disease was originally derived from the bovine species. He did not believe that less than 50 per cent. of all dairy cattle were affected with it, while the statistics which he had quoted showed that wherever there was a race of people without cattle phthisis was unknown. He believed, furthermore, that if all the cattle in this country were to be killed the disease would finally die out entirely here. In countries where dairy cattle were introduced for the first time it took a series of years for the disease to become established among the population, as was the case in Thibet and Ceylon; and, in the same way, if all the cattle were removed from a country phthisis would also disappear in the course of some years. Even after the disease had become firmly established, he did not believe that it could maintain its existence indefinitely after the removal of all cattle. He did not wish to rely on statistics except so far as they substantiated the main point that he made, that wherever cattle existed there phthisis also existed. As to the mortality among prisoners, etc., he was quite willing to acknowledge that the infection was derived from persons affected with the disease, and that the existing conditions were peculiarly favorable to the development of the disease. The practical outcome of the whole matter, to which he desired to call special attention, was that the prevalence of phthisis could undoubtedly be diminished by properly regulating by law the breeding of cattle, so that the in-breeding now so common might be done away with.

At the last meeting of the New York County Medical Association Dr. John Shrady read a paper on *Signs of the Moribund Condition*, in which he brought out a number of interesting points. He laid considerable stress upon prognosis, as being

a much neglected study, even though to the patient it was of paramount importance, as involving many questions of individual, legal and social importance. The dying state, he said, could never be arrested. Once begun, it could end only in one way. His conclusions were that, in general, the most trustworthy signs of death are those that appeal to the eye; that among these the respiratory function holds the first rank, both in cases of coma and asthenia, and especially where the two modes of death are combined; that the death by coma has a more extended period of duration; that the most valuable sign of inevitable dissolution is the up-and-down movement of the *pomum Adami*; that temperature changes deserve attention, particularly when the curves are sharp, high and continuous; that intermittent pulse is an early sign of death, particularly when not due to any disturbed action of the nervous system; and that deaths from syncope are too sudden to admit of much observation or study.

P. B. P.

The Causation of Pneumonia.

Dear Sir:—This is an attempt to summarize certain evidence presented in the valuable "Introduction to the Study of Pneumonic Fever" by Edward F. Wells, M.D., being published in THE JOURNAL, and to group that evidence relative to epidemics by seasons of the year with evidence relating to the increase and decrease, by seasons of the year, of pneumonia other than epidemic.

On pages 259-262 of THE JOURNAL for Feb. 23, 1889, Dr. Wells gives a table of chronology of epidemics of pneumonia, stating the country, the year, and the season of the year, in which each epidemic occurred. I have footed his column relative to the season of the year, and find the result as stated in my Table I as follows:

TABLE I.—The reported epidemics of pneumonia in the Northern Hemisphere during the 48 years, 1440-1888, reported by seasons, and estimated by months. (From data in a table on pages 259-60, THE JOURNAL, Feb. 23, 1889.)

Winter.			Spring.			Summer.			Fall.		
Dec.	Jan.	Feb.	Mar.	Apr.	May	June	July.	Aug.	Sept.	Oct.	Nov.
13	25	51	57	27	12	3	1	0	1	3	5
Total 89.			Total 96.			Total 4.			Total 9.		

The study of the subject by quarters of the year is not as satisfactory as by months, and especially as I wish to compare the result with my previous studies of sickness from pneumonia by months; therefore I endeavor to learn the probable grouping of epidemics by months.

In Table I, I find that the least number of

epidemics (4) occurred in the summer, and that the greatest number (96) occurred in the Spring. The quarter in which occurred the next to the least number was the fall, therefore the *month* of least epidemics must have been in the summer quarter, but nearer the fall than the spring, it must have been, then, in August. The month of maximum epidemics must have been in the spring, but nearer to the winter than to the summer quarter, therefore in March. Given the months of maximum and minimum epidemics, and dividing the epidemics actually reported in each quarter among the several months so that the month in each quarter to which the largest

TABLE 2.—The average per cent. of weekly reports stating presence of sickness from pneumonia in Michigan and average atmospheric temperature, by months, during the eight years, 1877-84. Also, of the reported epidemics of pneumonia in the Northern Hemisphere during the years 1440-1888, the numbers by months. (The data for the reported epidemics of pneumonia is from THE JOURNAL, Feb. 23, 1889, pages 259-60. The data relative to sickness from pneumonia and average temperature are from the Annual Report of the Michigan State Board of Health for 1885, pages 26 and 128.)

TABLE 3.—The average cases of sickness from "Respiratory Disease" per 10,000 of the native troops in India, and the average atmospheric temperature, by months, during the three years, 1883-85. Also, of the reported epidemics of pneumonia in the Northern Hemisphere during the years 1440-1888, the numbers by months. The figures for the reported epidemics of pneumonia are from data in THE JOURNAL, Feb. 23, 1889, pages 259-60. The figures for sickness from "Respiratory Disease" and for average atmospheric temperature are from data in the 20th, 21st and 22d Annual Reports of the Sanitary Commissioner with the Government in India.

	Jan.	Feb.	Mar.	Apr.	May.	June.	July.	Aug.	Sept.	Oct.	Nov.	Dec.
Sickness from "Respiratory Disease" in India	102.8	71.6	51.8	38.6	33.8	26.6	25.5	23.7	31.8	37.7	50.9	93.8
Average temperature in India	68.7	70.6	79.4	83.9	86.2	84.8	83.3	82.7	82.3	80.5	74.2	69.4
The reported epidemics of pneumonia.	25	51	57	27	12	3	1	0	1	3	5	13

probable numbers by months are as stated in the upper line of figures in Table I.

Having, now, the epidemics by months, it is possible to compare them by months with the atmospheric temperature, and with the sickness from pneumonia as recorded in Michigan for many years. This is made possible by Table 2

The epidemics all seem to have been in the Northern hemisphere, but many of them in climates much warmer than that of Michigan. Inasmuch as it is impracticable to learn just what the average corresponding atmospheric temperature was, it seems best to study the relation of the epidemics to the actual temperature not only in a cold climate, like that of Michigan, but also in a warm climate like that of India. Accordingly the relation in the warm climate is shown in my Table III.

The study of such relations as this of sickness to atmospheric temperature by means of Tables, is complicated because the changes in the sickness may not all be coincident with the temperature changes, but may lay behind them. For this, and other reasons the most satisfactory method of studying such subjects is by means of diagrams, accurately drawn to scale, so that the relations between supposed cause and effect in any one month and of cause or effect in each and every month of the year may be seen at a glance.

Dr. Wells says: "There can be no doubt as to pneumonic fever epidemic as well as sporadic—everywhere and always being due to the action of a single peculiar and specific morbid material." Without attempting to affirm or deny this, I respectfully submit that the evidence which he has supplied in his Table of Epidemics, taken with the evidence heretofore collected by myself,² seems to prove that pneumonia—"epidemic as well as sporadic—everywhere and always" is absolutely controlled by the atmospheric temperature, or by conditions associated therewith.

HENRY B. BAKER.

Lausing, Mich., March 18, 1889.

Intubation of the Larynx.

Dear Sir:—An editorial appears in the April 13th issue of your valuable journal, on intubation of the larynx, that conveys an impression that, I hope, was not intended. The impression conveyed is, that intubation being a bloodless operation, is readily consented to, and is performed early and often unnecessarily. Such an impression also prevails extensively among the profession, and it is often said, "Oh! well! all those cases would get well any way." Such statements are peculiarly aggravating when we

¹ THE JOURNAL, Feb. 23, 1889, p. 263.

² Published in article entitled "The Causation of Pneumonia" in Annual Report, Michigan State Board of Health for 1886, pp. 246-324 and in other articles on allied topics, in the past few years.

number is assigned shall be next to the quarter in which the larger number is reported, the

remember how many times we are called to perform intubation because the patients are too far gone for tracheotomy, too young, or because the cases are of a too malignant nature to sanction a cutting operation. It must be remembered that nine-tenths of all these cases are in consultation with other doctors, and we are called only as a last resort when all other measures have failed, and when it is evident that death must soon ensue. Many of these cases are moribund, unconscious and well nigh hopeless, others are young, and others again of a malignant nature, so that the favorable cases are few and far between; and yet it is said that the operation is performed early. Such a statement is a reflection not only upon the operator but upon the attending physicians as well.

To illustrate the condition of many of these patients, allow me to mention a few cases.

November 27.—I was called by Dr. O'Malley to see a little girl of 7 years suffering from semi-malignant diphtheria; nasal, pharyngeal and laryngeal. The parents at first objected to the operation, and emetics were repeatedly given in addition to other medication; these failing to give relief, and it being perfectly evident to the parents that the child was surely strangling, consent was given. The doctor acknowledged that the case was too unfavorable for tracheotomy. The child wore the tube four days and recovered completely.

November 30.—I was called by Drs. Steele and Jacques to perform the operation upon a baby 18 months old, "too young for tracheotomy." *Patient recovered.*

December 3.—I was called by Dr. G. W. Webster to operate upon a little girl 4 years old, with semi-malignant diphtheria with invasion of the larynx. The patient was surely dying and "too unfavorable for tracheotomy." The child wore the tube five days and recovered.

January 1.—I was called by Dr. Jacques. Patient 8 years old, moribund, unconscious, limp, and pulseless at the wrist. The tube was introduced without resistance and artificial respiration performed. The patient revived and fully recovered. The doctor stated the child would have been dead in ten minutes.

January 5.—Through the courtesy of Dr. A. L. Thomas, I was called to operate upon a baby 18 months old and moribund, "too young and too unfavorable for tracheotomy." Patient revived, returned to consciousness, but died two days later.

January 10.—Through the courtesy of Dr. Parsons, operated upon a baby 17 months old; moribund at the time of operating. Patient died twelve hours later.

January 18.—Through the courtesy of Dr. Miller, operated upon a baby fifteen months old, "too young for tracheotomy." Patient recovered.

March 12.—I was called by Dr. Kippax to operate upon a boy 7 years old, Drs. Guerin and Jacques being present. The patient was unconscious, comatose and actually dying, but revived and fully recovered.

March 14.—Through the courtesy of Dr. Simons operated upon a patient 5 years old, with malignant diphtheria of the nasal cavities, pharynx and larynx. Patient died from asthenia.

April 8.—Through the courtesy of Drs. Gatchell and Mitchel operated upon a little girl 8 years old, suffering from malignant diphtheria with invasion of the larynx. The patient was moribund, extremities cold, and clammy and pulseless. The patient fully revived, but died the next day from the malignancy of the disease.

April 24.—I was called to see a boy 4 years old a patient of Dr. Marks' who was present at the operation. The boy was upon the point of death from diphtheritic laryngeal stenosis. The child was unconscious, the lips were of a dark purple, almost black, the pulse could not be detected at the wrist, and the child was certainly dying. When the patient had reached this deplorable condition I was hastily summoned, and found the attendants hovering over the child waiting for the last gasp to prove that life was extinct. The operation was performed and artificial respiration resorted to before consciousness was restored. The child fully revived, but died as a result of the hypostatic congestion of the lungs. These are only a few cases among many of like nature, but a sufficient number to prove, I hope, that the operation is not performed early or unnecessarily. Yours respectfully,

F. E. WAXHAM, M.D.

240 Wabash Avenue.

Climatic Influence in Phthisis.

Dear Sir:—In a recent editorial (page 523) THE JOURNAL called attention to the importance of "knowledge concerning the elements that give special character to climate and their influence on the functions of the human body" . . . knowledge "essential" . . . to "every practitioner, who would do justice to those who depend upon him for advice." And yet, as indicated in the editorial, the records of *facts* necessary to give us such knowledge are not usually to be had; we usually obtain only the *opinions* of those who write on this subject, based upon experience which may be valuable, but which opinions, after all, do not greatly advance the science of climatological etiology. It was to supply such records of facts, the absence of which was deplored in the editorial just referred to and in the article by Dr. Denison mentioned therein, that the paper which followed Dr. Denison's at the International Medical Congress, was prepared and

read; I refer to the article entitled, "Relations of Certain Meteorological Conditions to Diseases of the Lungs and Air-passages as shown by Statistical and other evidence." The statistics included tens of thousands of weekly reports of sickness, and records of hundreds of thousands of deaths from phthisis and from disease of the air-passages, in this country and in other countries. These statistics were studied in connection with statistics of the meteorological conditions, and were found to be harmonious; and the writer considered it proved "that the rise and fall of [phthisis and] the diseases of the air-passages are controlled by the atmospheric temperature, and that this is accomplished mainly through the quantity of vapor of water abstracted from the air passages." In the discussion which followed these papers, the writer expressed the opinion that this was a general law,—that if there could be obtained records of phthisis and meteorological conditions in Colorado their relations would be found to be the same as has been found to be true elsewhere, wherever the subject has been studied. If any one doubts this generalization, what is needed is that the facts be recorded, in each locality respecting which there may be doubt, and that these records of facts be brought forward, that they may be studied by those of us who are interested in the subject. I wish most emphatically to indorse the plea in the article by Dr. Denison and in the editorial, for the bringing forward of *facts*, accurately stated by weight, measure or number so that they may be available for building up the science of tiology or of climatological therapeutics.

By this mail I send you a copy of the paper containing the mortuary, morbidity and meteorological statistics which I have mentioned.

Very respectfully, HENRY B. BAKER.
Lansing, Mich., April 19, 1889.

BOOK REVIEWS.

ELECTRICITY IN THE DISEASES OF WOMEN, with Special Reference to the Application of Strong Currents. By G. BETTON MASSEY, M.D., Physician to the Nervous Department of Howard Hospital; late Electro-Therapist to the Philadelphia Orthopædic Hospital and Infirmary for Nervous Diseases, etc. 8vo, pp. viii, 210. Philadelphia and London: 1889.

Taken as a whole the work done by Dr. Massey in his "Electricity in the Diseases of Women," is very satisfactory, and helps to fill a deeply-felt need of the practitioner, viz: a modern scientific work on electricity. The rapid development and recent scientific demonstrations of this subject have rendered former authorities almost absolute,

and as yet comparatively nothing has arisen to take their place.

While Dr. Massey's book covers but a limited portion of this vast subject, it still is in most respects, scientific and will prove of assistance to the practitioner who is desirous of employing electricity as a therapeutic agent.

But little space is occupied by the consideration of the physics of electricity proper, but the detailed experiments given in chapters III and IV are well conceived, and will do much toward clearing up this intricate subject to the minds of the uninitiated, and they should be thoroughly mastered by the practitioner who is ambitious to employ electricity intelligently. The remainder of the book is mainly a compilation from articles which have appeared from time to time in various medical journals during the past three years, and in most respects lacks originality save in the detail of cases.

Many of the more ordinary difficulties met with by the gynæcologist, such as menorrhagia, sub-involution, hyperplasia, pelvic induration, pelvic pain—including obstructive and nervous dysmenorrhœa—uterine stenosis, intermenstrual neuralgia, uterine displacements, amenorrhœa and hydrosalpinx, all are treated by the electrical means indicated, and with results which coincide with those reported by the majority of operators employing similar methods.

By far the greater portion of the book is devoted to a description of Apostoli's work. In chapter V. is considered the intra-uterine galvano-chemical cauterization (Apostoli's operation), as employed in the treatment of fibroid tumors and chronic metritis. The different steps of the operation are clearly described, and the electrodes and appliances illustrated. It is to be regretted in this connection that the author recognizes no form of intra-uterine flexible electrodes other than the stiff platinum sound, because in consequence a greater proportion of cases of filroid tumors with tortuous canals must submit to the more dangerous operation of galvano-puncture. This subject naturally forms the most important portion of the book, and is worthy the time devoted to it.

A chapter is devoted to the consideration of Extra-Uterine Pregnancy, electrically treated, and one to "Contra-indications and Limitation to the use of Strong Currents."

To the conservative practitioner this book offers a safe and effectual method of treatment for many difficulties which have in the past been a serious perplexity to him, while to the unscrupulous operator it should come as a grave reproach for the severe measures so often unnecessarily and unjustifiably employed, and it is to be hoped that through its influence some little may be accomplished toward righting this great wrong.

F. H. M.

MISCELLANY.

ILLINOIS STATE MEDICAL SOCIETY MEETING at Jacksonville, May 21, 1889. The following action was taken by the Society at the last meeting:

WHEREAS, It has been demonstrated by the experience of the past years that the present constitution, by-laws and rules of the Illinois State Medical Society have become totally inadequate to a proper and satisfactory carrying out of the aims and purposes for which said constitution, by-laws and rules were formulated; be it

Resolved, That a committee of five members be appointed, whose duty it shall be to secure from the Secretary of State a charter for this Society under the law providing for the incorporation of organizations, not for pecuniary profit.

Resolved, That this committee be empowered and is hereby authorized to draw up a new constitution and new by-laws for the future government of this Society.

Resolved, That said committee be required to mail every member of this Society a printed copy of the proposed constitution and by-laws at least sixty days prior to the next annual meeting, in 1889.

Resolved, That the consideration, amendment and adoption of the proposed constitution be the special order at its next meeting, immediately following, as nearly as possible, the delivery of the President's address.

It is specially important that there be a full attendance at the meeting this year, not only of the permanent members of the Society, but of representatives from all local societies of all parts of the State, as many important questions will come up affecting the future of the Society and its influence on the medical interests of the whole State.

Those expecting to present volunteer papers should notify the Committee of Arrangements as early as possible.

The Committee of Arrangements has secured reduction of railroad fare for members and delegates, on the certificate plan. Each delegate should get certificate from his local agent, of having paid full fare to the meeting.

The Constitution of the Society requires all members and delegates to register and present their credentials before participating in any business of the meeting. Registration will begin at 9 o'clock, A.M., on Tuesday, at the Hall. It is desired that as many as can do so, will register before the Society is called to order.

BARIUM sells for \$975 a pound, when it is sold at all, and calcium is worth \$1,800 a pound. Cerium is a shade higher—its cost is \$160 an ounce or \$1,920 a pound.

HEALTH IN MICHIGAN, APRIL, 1889.—For the month of April, 1889, compared with the preceding month the reports indicate that intermittent fever, rheumatism and remittent fever increased, and that influenza, pleuritis and pneumonia decreased in prevalence.

Compared with the preceding month, the temperature in the month of April, 1889, was higher, the relative humidity was less, the absolute humidity and the day and the night ozone were more.

Compared with the average for the month of April in the three years, 1886-88, measles and inflammation of kidney were less prevalent in April, 1889.

For the month of April, 1889, compared with the average of corresponding months in the three years 1886-88, the temperature, the absolute humidity, the relative humidity, the day ozone and the night ozone were about the same.

Including reports by regular observers and others, diphtheria was reported present in Michigan in the month of April, 1889, at 23 places, scarlet fever at 43 places, typhoid fever at 5 places, measles at 14 places, and small-pox at 1 place.

Reports from all sources show diphtheria reported at 6 places less, scarlet fever at 11 places more, typhoid fever at 3 places less, measles at 2 places more, and small-pox at 4 places less in the month of April, 1889, than in the preceding month.

EPICYSTIC SURGICAL FISTULÆ FOR CYSTOSCOPIC EXPLORATION; IN- TRA-VESICAL TREATMENT AND DRAINAGE.

Read before the State Medical Association of Alabama, April 11, 1889.

BY JOHN D. S. DAVIS, M. D.,
OF BIRMINGHAM, ALABAMA.

Epicystotomy has become an established and recently practiced procedure, and the dangers incident to opening the bladder through the abdominal wall is so slight that patients suffering from almost any vesical trouble are encouraged to have the bladder opened for diagnostic purposes and treatment at a time when the general health remains unimpaired; a practice which, a few years ago, would not have been resorted to by the most aggressive surgeon.

Catarrh of the bladder, irrespective of its cause, is always followed by a series of consecutive pathological changes which, independently of the partial or complete interruption of the passage of the urine, tend to destroy life. A dilatation of the bladder and ureters by retention of urine may give rise to such a degree of distention as to destroy life from suspension of important functions by mechanical pressure. During the stage of inflammation a paretic condition may occur, the blood-vessels in the vesical wall lose their support, and transudation and exudation take place into the paravascular tissue, which, combined with capillary stasis attending this stage of the disease, results in sloughing, infiltration, pyæmia, peritonitis and death. The damming up of the urine may, and does often, cause surgical-kidney, epididymitis and tetanus.

The treatment of chronic vesical catarrh resolves itself into a consideration of the causes producing the disease, many of which, the presence in excess of certain inorganic constituents of the urine, stone, stricture and hypertrophy, are capable of correction; whilst others—such as malignant tumors and certain conditions of the prostate—may only admit of a palliation of the symptoms to which they give rise and the removal of which must be the first object in treat-

ment. But when a paretic condition of the bladder exists provision must be made for the complete continuous emptying of the viscus; its thorough cleansing by frequent irrigation with hot sterilized water; and the promotion of a healthy tone in the mucous membrane and muscular structure of the bladder. The frequent introduction of catheters for drawing off residual urine and washing out the bladder has been productive of much harm, and, instead of giving relief, proved to be, by reason of their frequent introduction into the inflamed bladder to draw off the urine two or three times a day, a source of immediate and alarming symptoms. These facts are cogent reasons for adopting surgical means in all cases of intra-vesical troubles as soon as a diagnosis can be made, and often when it can not otherwise be made, for the complete emptying of the bladder, thorough cleansing, diagnosis, and intra-vesical treatment.

The epicystic surgical fistula is designed for drainage, intra-vesical treatment and cystoscopic exploration, and may be divided for consideration under the following heads:

I. Definition of epicystic surgical fistula.

II. Surgical resources in the formation of the epicystic surgical fistula.

1. Preparation for the operation.
2. Anæsthesia.
3. Position.
4. Incision and opening bladder.
5. Intra-vesical exploration and treatment.
6. Toilette and after-treatment.

III. Advantages of the epicystic surgical fistula.

1. Cystoscopic exploration.
2. Intra-vesical treatment.
3. Drainage.

I.—DEFINITION OF EPICYSTIC SURGICAL FISTULA.

Epicystic Surgical Fistula is the title here given to a supra-pubic fistula into the bladder created by the surgeon for exploration, intra-vesical treatment and drainage. A fistula, which, acting as an artificial urethra, is capable of giving free access to the inside of the bladder for cystoscopic exploration to provide a ready, convenient and comfortable means of emptying the

bladder at will, and gives the surgeon a competent opening into the viscus for intra-vesical applications.

It constitutes an essential element in the speedy and complete evacuation of the contents of the bladder in all epicystic operations, and imitates nature in the restoration of its own continuity and repair as the pathological changes within the bladder subside.

II.—SURGICAL RESOURCES IN THE FORMATION OF THE EPICYSTIC SURGICAL FISTULA.

1. *Preparation for the Operation.*—The presence of two assistants, though not necessary, may be of valuable aid. A temperature of 80° or 85° Fah. should be maintained in the operating room from the beginning to the end of the operation. All hair is to be shaved from the pubis and all the details of antiseptic surgery are to be carried out so far as cleaning the pubis and abdomen. The bladder is emptied and thoroughly washed with warm water. When the water returns clean the bladder is slowly distended with warm sterilized water thrown into the bladder by means of a fountain syringe, with nozzle in urethra—a degree of pressure sufficient to distend the bladder to its utmost capacity—which can never be too great for the resistance of the bladder. It is better to fail in filling the bladder than to distend the bladder beyond the limit of competency. Indeed it is not necessary to fill the bladder to any degree of resistance. I have operated when the bladder was in an irritable condition and would not tolerate distention greater than the capacity of two ounces, and had no difficulty in avoiding the pre-vesical fold of peritonæum of finding the bladder. The water is secured in the bladder by tying the penis at the base with a rubber tube.

A colpeurynter is next to be well oiled and inserted into the rectum—the rectum having been previously emptied by enema—and filled with warm water. This distention brings the bladder into view above the pubis.

2. *Anæsthesia.*—My preference for chloroform is the result of my own personal experience with it. It is not free from objections as its depressing effect on the heart is well known. The operation usually occupies fifteen minutes; and, hence, its prolonged use would be unnecessary and uncalled for. The objection to ether is the suppression of the excretions and the frequency with which bronchitis is produced when administered to persons advanced in years. The best course to pursue, when the operation is prolonged, is to follow the use of chloroform by ether. The patient must be kept profoundly under the influence of the anæsthetic from the first incision until the superficial wound is closed.

3. *Position.*—The patient is placed on the back on an ordinary operating table with the legs extended as if in a position for perfect comfort and

rest. Many surgeons claim advantages in the position recommended by Trendelenburg. Eigenbrodt emphasizes the fact¹ that the elevation of the pelvis in Trendelenburg's position² helps the surgeon to avoid the pre-vesical peritoneal fold at the time of the incision of the bladder.

I have employed this posture for intra-vesical operation by means of the supra-pubic incision with no advantage over the ordinary flat-back position. With two openings in the bladder for a continuous stream of clear water I have no trouble in illuminating every part of the bladder with the electric surgical light and thus enabled to examine the entire intra-vesical wall. Undoubtedly the position recommended by Trendelenburg, possesses advantages which to the author more than myself, makes it highly ideal. As for myself I prefer and recommend the flat-back position.

4. *Incision and opening bladder.*—A perpendicular incision three or four inches long is made in the median line above the symphysis pubis. The recti muscles are separated to symphysis. If the pyramidalis are in the way, the fibres should be cut. The transversalis fascia is divided on a grooved director from symphysis to within one inch of upper margin of superficial wound. Instead of following Guyon's manœuvre, I catch the bladder with a tenaculum on a line with the symphysis, through the pre-vesical fat, and cut through with a bladder knife into the bladder with one smooth, clean incision, to prevent undue disturbance of the cellulo-adipose tissue between the bladder and pubis and avoid infiltration. I have never seen a case where it was necessary to put up the pre-vesical fat, and with it the peritoneal cul-de-sac. If the bladder is caught on a line with the symphysis and cut downwards, no fears need be had for the peritonæum. Cutting this pre-vesical fat prevents its after dropping down over the opening into the bladder and acting as a valve to prevent easy escape of urine and causing infiltration. And, too, such a procedure gives a smooth incision throughout, and it is almost impossible to have infiltration, even when no drainage tube is left in the bladder and the urine is left to flow out through the fistulous track and taken up by a layer of absorbent cotton. In making the incision into the bladder, no attention is to be paid to any vein or veins which are sometimes met with. If cut, they will stop bleeding when the bladder is dropped back and the rectal bag removed. The operation is usually bloodless in the sense of hemorrhage. I have operated without the patient losing more than one drachm of blood.

5. *Intra-vesical exploration and treatment.*—The finger is carried into the bladder and a

¹l. c., p. 72. Cf. Lang, Med. News, Dec. 4, 1886.

²In Trendelenburg's position the patient's legs are held over the shoulders of an assistant with the body resting on an incline table, much in the position which hogs are swung for spaying.

thorough search made for any tumors, villous growths or foreign bodies. The bladder is now emptied and the rubber around penis untied and the bladder well washed out with hot sterilized water. The bladder can now be examined with the cystoscope and surgeon's electric light. If tumors be found if practicable they should be removed; villous growths and any foreign body found should be removed. If nothing is found in the bladder, the surgical fistula, in the absence of malignancy, will be all that is required to relieve the cystitis.

6. *Toilette and after-treatment.*—The bladder is allowed to drop back into the pelvis and the superficial wound so closed by two sutures (including the skin and superficial fascia only), in the lower portion of the incision and one in the upper portion of the incision, as to leave a fistulous track of equal size from bladder to juncture of upper third and middle third of the superficial incision. A large rubber catheter is now to be introduced into the bladder through the opening and its distal extremity allowed to enter a urinal placed in the bed between the patient's thighs, or preferably at the patient's side. Professor F. Trendelenburg, director of the surgical clinic of the University of Bonn, proposed, for draining the bladder in supra-pubic lithotomy, the T-tube in latero-abdominal position and open wound treatment as the simplest, safest and best. He makes an antiseptic dressing of iodoform gauze around the T-tube. There can be no real necessity for a tube of any kind to be introduced into the bladder for the purpose of conveying the urine from the bladder to prevent infiltration, irritation of superficial fascia and soiling of dressings.

If the urine is kept acid, by the administration of citric acid or some other more palatable acid drink, no better antiseptic than the acid urine can be secured for the constant bath of the parts. It should be allowed to flow out through the wound and absorbed by a pad of absorbent cotton placed loosely over the wound, and removed as often as soiled by the outflowing urine. By this method of emptying the bladder, no possible small amount of urine can be impeded in its outward flow, which is the case around and outside of the tube, when catheter or tube is left in for any length of time—a source of no little annoyance at times. This little collected or retained urine, around the outside of the tube alone, I have seen produce a hard chill and elevation of temperature, and become for the time an immediate, alarming and aggravating source of trouble. I never have seen the skin made sore or chafed by the outflowing urine in epicystotomy, or from its after-escape through the surgical fistula.

The bladder should be washed out twice daily with hot sterilized water, by means of a fountain syringe, with its nozzle introduced into the

urethra, the water escaping through the epicystic fistula and guided into a bed-pan under the patient. The superficial stitches are taken out at the end of a week, and intermittent catheterization by the fistula is then resorted to for the sole purpose of training the fistula and prevent its rapid closure. It is not necessary to catheterize for the purpose solely of drawing off the urine. In one case I never drew the urine save for the purpose of analysis, but occasionally introduced a rubber bougie to prevent the closure of the fistula. The drainage by the fistula alone is admirable, and the fistula will be well formed in twenty or thirty days, competent to retain urine without dripping and to allow its escape in a good projecting stream at will. With no tearing of the tissues, and with a clean cut, the drainage is perfect and the dangers are *nil*.

III.—ADVANTAGES OF THE EPICYSTIC SURGICAL FISTULA.

1. *Cystoscopic Exploration.*—Nitze has by means of the cystoscope been enabled to diagnosticate tumors of the bladder in nine cases in which rectal palpation, the sound and other means had furnished negative results. One of the great difficulties in the cystoscopic exploration of the bladder is the presence of pus, mucus, and sometimes blood, which renders it exceedingly difficult to maintain a translucency of the fluid used to distend the bladder. By means of a simple fountain syringe a constant current of clear water may be kept within the bladder so essential to a complete observation of the trigonum Lieutaudii, the most interesting part of the viscus, the ureters; and to examine any affection of that viscus. The fistula may be made for temporary purposes of cystoscopy by the Peterson-Guyon-Perier operation; but I can see great advantages from a different operation, by Dr. Hunter McGuire, the object of which tends to eliminate as well as detect the trouble within the viscus; and, too, in the final construction of a permanent fistula, gives an easy after-method of exploration, and makes a better artificial method by reason of its length and extension upwards of two to three inches. Diagnostic purposes are met by the possibility of immediate detection of all local conditions, such as tumors, calculi, foreign bodies, neoplasms, the collection of fluids from the ureters, etc.

2. *Intra-vesical Treatment.*—Having by means of the epicystic exploration revealed the true nature of the intra-vesical trouble, the treatment resolves itself into the immediate necessities of the case. For instance, prostatectomy may be necessary, villous papilloma may be found and should be remedied; predunculated growths may be found which should be removed by the scissors or Paquelin's cautery, etc. In such cases, the opening in the bladder sufficient to introduce the

finger, should be enlarged downwards under the symphysis pubis, and the operation indicated should at once be performed. The object of the formation of the permanent surgical fistula is to meet the after indications in such operations, the details of which does not properly come within the province of this discussion. However, it is sufficient to state, what is reasonable and practicable, that a better means by which the intra-vesical wall can be reached and treated therapeutically has not yet been devised.

3. *Drainage.*—Permanent after-drainage in all intra-vesical operations cannot be necessary; but is highly essential to secure good and sufficient drainage until the paravascular tissue is disengorged, the cystitis is relieved, and the urine becomes normal and passes per urethra unobstructed. And until this end is attained complete artificial arrangement for the escape of the contents of the viscus must be made. In such cases of prostatic hypertrophy or malignant growths when removal of the obstruction is impossible or contra-indicated, the epicystic surgical fistula is clearly indicated, and essentially necessary. It meets every possible indication for local treatment and gives the only controllable, ready and free drainage to viscus and kidneys. Urinary back pressure as the result of incompetency of the urethra from the various immovable prostatic troubles is often an immediate and remote cause of surgical-kidney, which can only be removed or relieved by supra-pubic drainage. In conditions of the bladder, of long standing cystitis, as in the case reported by me in the *Virginia Medical Monthly*,³ in which the urethra, though made competent by cutting, was not sufficient to keep the bladder emptied without catheterization—a procedure which kept up a constant vesical inflammation, which, combined with capillary stasis attending the inflammatory process resulted in paresis.

I now have the pleasure of introducing that case, Mr. T. A. Nixon, to you fifty-eight days after the operation. His condition to-day is sufficient guarantee for all I have said in favoring the formation of an epicystic surgical fistula for the relief of chronic vesical catarrh. The result in this case is more than I promised. He can retain his urine several hours and without dripping of urine or pain to bladder. Urine completely under control and bladder relieved of pain.

A CASE OF SENILE CHOREA; WITH REMARKS.

Read before the Philadelphia County Medical Society, March 13, 1889.

BY J. M. ANDERS, M.D.,
OF PHILADELPHIA.

By the majority of authorities, chorea in aged persons is believed to be rare. Not many years

ago, writers on the subject of chorea held that old age was of itself conclusive evidence that this disease did not exist in any given case. But since the collection and publication of twelve cases by Robert Saundby,¹ in 1884, the fact that senile chorea is a distinct affection can no longer be doubted. From ordinary chorea, which usually occurs during the period of approaching puberty, it differs widely as to etiology, and, probably, pathology as well. Believing that the extreme rarity of the occurrence of chorea in the aged fully justifies those practitioners of medicine who meet with it in publishing an account of their cases, I make no apology for placing on record the following case, which came under my notice at the Episcopal Hospital. The resident physician, Dr. G. B. Tullidge, has kindly furnished notes of the case, to which only slight additions have been made.

J. B., æt. 60 years, occupation cloth-cutter, was admitted to the medical ward of the Episcopal Hospital August 27, 1888. Patient, prior to present trouble, was in most excellent condition. He has had small-pox, three attacks of gonorrhœa, and acute articular rheumatism, all over thirty years ago. His habits have ever been temperate, although he has occasionally indulged in alcoholic drinks. His father, of sound body, was drowned. His father's brother died of old age at 90 years, and his mother, prior to death from cholera, in 1847, had always been in vigorous health.

He attributed the present attack to exposure while at Atlantic City in July, 1887. One hot night he slept with his head on the sill of an open window; the wind changed, the temperature fell, and he awoke cold, chilly, and suffering with pain and stiffness in the muscles of his neck. From that morning began the symptoms now complained of. The patient, an American by birth, has always lived in Philadelphia, is 5½ feet tall, and spare, though as well nourished as he has ever been. He comes complaining of his inability to keep at rest while awake, of oft-recurring attacks of fidgets. The attacks have so increased in severity and frequency as to compel cessation from work. There is a slightly increased prominence of the nape of the neck, though no actual deformity of the cervical portion of the spinal column is discernible; and his head is constantly held more rigidly erect than would be expected of a man of his age. During an attack the muscles of the neck, back and chest undergo irregular spasmodic contractions, causing shrugging of shoulders, twitching of arms, and well-marked jerking of head, which is thrown in the backward direction. The face also is thrown into movement, and exhibits characteristic choreic grimaces, with rolling of eyeballs. As the attack proceeds, the diaphragm becomes similarly affected, causing great difficulty in breathing. Inspirations are jerky and irregular.

³ *Virginia Medical Monthly*, April, 1889. *Alabama Medical and Surgical Age*, April, 1889. *New York Medical Journal*, April 13, 1889.

¹ *Lancet*, November 24, 1884, quoted by Sinkler.

The accompanying dyspnoea is always a most prominent and distressing symptom. During the attack, great pain is felt in the back of the head and neck. Each exacerbation lasts from one to four hours. During the intervals he feels quite well, and has only an occasional involuntary twitch. Insomnia is very great, and night follows night before he procures refreshing sleep. The intervals of quiet vary considerably in length; one, two, three or more days may intervene between these attacks. His appetite is fair, and his digestive functions are performed with apparent vigor and regularity. The action of the heart is constantly rapid, the pulse-rate ranging from 110 to 120 per minute, but there are no evidences of organic valvular disease detectable. Neither are there any characteristic subjective or objective symptoms present, pointing to any nervous trouble other than chorea. There is no dementia.

When admitted he was placed on a mixture of quinia, iron and strychnia; also was given 10 grs. of bromide of potassium every three hours. This treatment was continued for three weeks without benefit. The bromide of potassium has been mentioned by Charcot as being of service in this disease. Arsenic, which was administered both by the gastro-intestinal route and hypodermatically, proved valueless, as did also antifebrin given in doses of grs. iv every three hours. During the attacks, hypodermatic injections of morphia gave relief, causing sleep. The hydrobromate of hyoscin—a remedy recommended by Dr. S. Weir Mitchell, seemed to have a beneficial effect when first used, though it soon lost its virtue.

But, though treatment was apparently of no avail in this case, Charcot's view that chorea in the aged is incurable is not supported by all of the facts, since Dr. Russel relates a case that recovered at the expiration of three months, from the use of sulphate of zinc.

Dr. Sinkler has reported two cases, one of which recovered in four months. Still another case, first seen by Dr. Saundby when the patient was 50 years of age, suffering from left-sided chorea of an intermittent form, again fell under his observation when 66 years old, and at this time was almost cured.

Is senile chorea due to emotional causes? The emotional theory was advocated by Charcot in his famous lecture bearing the caption "Chorea in Old People."² But, as pointed out by Saundby, this view must, in the light of facts more recently observed, be abandoned. The two cases reported by Charcot (*loc. cit.*) were demented; also a case reported by E. J. Davis,³ and still another by M. Bacon, in which instance the patient had chronic mania.⁴ Thus, in a total of thirteen recorded cases, in all of which the mental condi-

tion was noted, four were demented—less than one-third.

Dr. Saundby saw three patients suffering from this disease, all of whom had advanced degeneration of the arteries. This observer believes "that it will be found that the pathology of this disease is some actual structural change, such as small hæmorrhages in the corpus striatum, and that it is not merely a functional derangement." In my own case there were present evidences of commencing atheroma. Of all the collectable cases, only four showed this condition—too small a proportion to base thereon positive conclusions.

The influence of sex may be shown to be considerable, since in eleven of the thirteen cases reported, the sex has been noted, and of these eight were males, three females. This would appear to be an exact reversal of the influence of sex in chorea occurring among children, for in the latter, according to the statistics of Dr. Wharton Sinkler,⁵ and others, the ratio is about three to one in favor of the girls.

Of the thirteen cases, only three were associated with heart disease, a fact showing but a feeble, if any, connection between senile chorea and cardiac affections. Not more than two of the total number gave a history of previous rheumatism. A final point to be made is that any theory of the pathology of chorea in the aged, based upon the meagre data at present attainable, must be purely speculative.

DR. WHARTON SINKLER: I have recently had the opportunity of seeing this patient of Dr. Anders, at the Philadelphia Hospital, where he is now under the care of Dr. Lloyd. The movements seem to be pretty much as they were when he was at the Episcopal Hospital. I think that cases of senile chorea are not quite so rare as one would suppose from the literature of the subject. I have frequently seen in old persons an irregular choreic movement of the extremities. I have now under my care an old gentleman, aged 80, in whom there are choreic movements of the left arm and leg. On inquiring in reference to the duration of this movement, I learned that it had not been before observed either by the patient or his relatives. In this case there was a transient attack of right hemiplegia a couple of years ago. In senile chorea I think that there must be an organic lesion, due probably either to small hæmorrhages or embolism in the corpus striatum.

DR. WILLIAM OSLER: I think that senile chorea must be entirely separated from ordinary juvenile chorea. Almost all cases of senile chorea are probably associated with organic changes, whereas the evidence is uniformly in favor of the view that the chorea of children is very largely a functional disorder.

DR. ANDERS: I have in my paper pointed out

² Medical Times and Gazette, 1873, vol. i, p. 245.

³ "Case of Chorea in the Aged," Medical Times and Gazette, vol. ii, p. 447.

⁴ Quoted by Saundby.

⁵ Pepper's System of Medicine, vol. v, p. 441.

that the chorea of the aged differs widely from chorea of childhood. I notice the influence of sex, and the fact that in children the results of treatment are, as a rule, quite satisfactory, while in the aged, with the exception of one or two instances, treatment has had but little effect. This would seem to indicate that there was some pathological lesion present in the chorea of aged persons to explain the difference in the results of treatment.

HYDROPHOBIA.

Read in the Section on Anatomy, Physiology and Pathology, of the Medical and Chirurgical Faculty of Medicine.

BY WILLIAM H. WELCH, M.D.,
CHAIRMAN OF THE SECTION.

[Reported by DR. WILLIAM B. CANFIELD]

Although since Pasteur's first publications on this subject, it has received the widest ventilation in medical journals, no apology is needed for a fresh critical review, so rapid are the additions to our knowledge and to such an extent does the estimation of the value of much of Pasteur's work depend upon results which can be determined only by the lapse of time. Although Pasteur's preventive inoculations against hydrophobia constitute the central point about which controversy has waged, it is not to be forgotten that Pasteur's discoveries and the investigations aroused by them have shed much light in many directions upon one of the most mysterious and fatal diseases. We are better able now than ever to consider the efficacy of the Pasteurian inoculations against hydrophobia.

He reported the results of the post-mortem examinations he had made in three cases of hydrophobia in human beings. In one case he had made serial sections of the medulla oblongata and pons from the 2nd cervical nerve upwards. The lesions in this neighborhood were small hæmorrhages, accumulations of leucocytes in large numbers in the peri-vascular lymph spaces and in scattered foci in the neroglic and thrombi, composed of blood-plates and of leucocytes in small blood-vessels. These lesions were for the most part microscopical and their extent and distribution could be determined only by the examination of a large number of sections from different parts. The lesions were especially well marked in and near the nuclei of origin of the spinal accessory, pneumogastric and glosso-pharyngeal nerves, and in the motor nucleus of the trigeminus. Cases have been reported in which even more extensive lesions than those have been found, their severity depending apparently in large measure upon the duration of the disease. While it cannot be claimed that these lesions are peculiar to hydrophobia, or by themselves suffice for its anatomical diagnosis, it is incorrect to suppose that hydrophobia is a disease without demonstra-

ble anatomical lesions which bear a manifest relation to the symptoms of the affection.

Far more important than this the addition to our knowledge of the pathological anatomy of rabies following Pasteur's discoveries, are the contributions to a better comprehension of the causation of the disease. Before Pasteur's publications on hydrophobia, dating from 1881, about all that we knew of the virus of rabies was that it is contained in the salivary glands and their secretions and that infection often follows the bites of rabid animals. We now possess valuable information concerning the properties of the rabid virus, its distribution in the infected body, the manner of its transmission, the singular differences in its action, according to the seat of its inoculation, and the means for producing immunity against its invasion.

Although there is no reason to doubt that the infectious agent in the virus of rabies is a micro-organism, no actual demonstration of this organism has yet been made. From material obtained from a series of rabbits which were inoculated at the Pathological Laboratory of the Johns Hopkins University with hydrophobic virus obtained from the medulla oblongata of a man dead of the disease, and which served to confirm the statements of Pasteur as to the behavior of these animals when inoculated with the rabid virus, efforts were made to demonstrate, both in the tissue and by means of cultures, some specific micro-organism, but with entirely negative result. While we are not acquainted with the specific organism causing hydrophobia, we know many of its properties.

The virus of rabies is destroyed by comparatively low temperature, exposure for one hour to a temperature of 50° C. [122° F.] sufficing for this purpose. It is killed in a short time by drying, certainly within four days when exposed in thin layers capable of rapid desiccation. It is destroyed by exposure to the direct rays of the sun, even when surrounded by conditions preventing much elevation of temperature. According to Babes, the virus is more resistant to the action of corrosive sublimate and carbolic acid than most micro-organisms, but it usually loses its infectious properties after exposure for three hours to the action of 0.1 per cent. sublimate, or of 1 per cent. carbolic solution. Galtier has pointed out the important fact that the virus of rabies may be demonstrated after forty-four days, and perhaps longer, in the cadavers of buried animals. A practical means of preserving the virus is to place the brain or cord of the infected animal in pure glycerine, which may be diluted with water, and should be occasionally changed.

It has been ascertained that the occurrence of infection with rabies depends largely upon the part of the body and the character of the tissues into which the virus is inoculated. The disease

always develops after inoculation of the virus into the brain or upon its surface, or into the eye, the period of inoculation being shorter and more definite after subdural inoculations. Inoculations into the substance of nerve trunks appears to be equally successful in rabbits, but somewhat less certain in dogs, although even with the latter inoculation into the pneumogastric nerves does not fail. Intravenous injection does not produce the disease in the ruminants unless very large quantities are used, and may fail in rabbits and especially in dogs. Especial importance attaches to the behavior of subcutaneous injections of the virus of rabies. Dogs often resist infection from injection of considerable quantities of even the most intense virus into the subcutaneous tissue. Ferran's super-intensive method of producing immunity in human beings, is to inject at once the strong virus into the subcutaneous tissue, and this has been done in over 200 cases without injury. If the injection be made into muscular tissue infection is more likely to follow. DiVestea and Lagari have shown that while simple subcutaneous injections are often unsuccessful in producing rabies, the application of the virus to the divided ends of nerve filaments in a cutaneous wound is generally efficacious in causing the disease. Although deep and severe bites of rabid animals are the most dangerous, hydrophobia may result simply from a mad dog licking a scratch.

One of the most important discoveries of Pasteur is the demonstration of the fact that in animals or human beings which have died of hydrophobia the virus is contained most abundantly in the central nervous system, and especially in the medulla oblongata. It is found constantly also in the salivary and lachrymal glands, sometimes in the pancreas, but it is usually absent from the blood, kidneys, spleen and liver. Only exceptionally is it present in the mammary glands and the neck. It is very rarely transmitted to the fœtus through the placenta.

There has been considerable discussion as to the manner in which the virus is conveyed from the seat of inoculation to the central nervous system. The evidence points to the transmission of the virus along the nerve, in fact it is claimed by Helman and others that the virus is capable of multiplication in nervous substance. Roux and others have found the virus present in the nerves of a bitten extremity when it has been absent in corresponding nerves of the opposite side. By killing animals at the proper period, it has been ascertained that after inoculation in the tail or posterior extremities the virus makes its appearance in the posterior part of the spinal cord sooner than in the medulla oblongata, while the reverse holds true when the inoculation is made in the head or posterior part of the body. These observations, taken together with the inefficiency of intravenous injections, and the absence of the

virus from the blood, lead to the conclusion that the virus passes along the nerve trunks, although we have no information as to how this is accomplished.

It is a significant fact, which should be remembered in judging the results of Pasteur's treatment, that there is a period of so-called latent development of the virus in the central nervous system. In rabbits inoculated with the strongest virus (*virus fixe*), the period of incubation is six days, but as early as the fourth day the virus has been found in the medulla oblongata. Doubtless, therefore, in human beings, the virus is present for a longer or shorter period in the central nervous system before any characteristic symptoms of rabies appear. Careful observation has shown that in rabbits this period is not really a latent one, but it is accompanied by elevation of temperature, increased frequency of respiration, slowing of the pulse-rate and loss of weight.

Dr. Welch said that there can no longer be any question that it is possible to render animals immune against rabies both before and after inoculations which would otherwise cause the disease. The independent and careful experiments of Ernst in this country are free from all partisan bias and have amply confirmed the statements of Pasteur on this point. The methods employed by Pasteur for protective inoculation against hydrophobia have been so often and so fully described in medical and other journals that Dr. Welch did not consider it necessary to repeat the description on this occasion. These inoculations are most effective in preventing the disease when undertaken soon after the reception of the poison with a large quantity of virus, and with the speedy employment of material containing the strongest virus (*virus fixe*). Animals may be rendered immune by single injections into the blood or the subcutaneous tissue of a large quantity of strong virus, whereas dogs which are bitten by mad dogs and which do not develop the disease, as often happens, are not left immune. Dogs which have once been rendered immune against rabies may preserve this immunity for at least two years, and doubtless for a longer period.

Pasteur attributes the immunity to the action of some substance which he calls "*matière vaccinale*," contained in the virulent material but not identical with the microorganism causing rabies. That immunity against infectious disease may be secured by the injection of chemical substances produced by the growth of specific bacteria, was first demonstrated by Salmon and Smith in the case of hog cholera, and has been subsequently demonstrated by Roux and Chamberland for malignant œdema and by Wooldridge for anthrax. It has not yet been found possible to prove conclusively the correctness of Pasteur's supposition in the case of rabies, but there is much which speaks in its favor.

Encouraged by the results of his experiments upon animals, Pasteur, in July, 1885, first applied to a human being his method of preventing hydrophobia by successive inoculations of the virus contained in the rabbit's medulla subjected to drying for different periods. During the years 1886, 1887 and the first half of 1888 there have been treated under Pasteur's supervision, either by the simple or by the intensive method of inoculation, 5,374 persons who have been bitten by animals either proven or suspected to be rabid. The mortality from hydrophobia, including even the cases which developed within a day after the cessation of treatment, was, in 1886, 1.34 per cent.; in 1887, 1.12 per cent.; in 1888, .77 per cent. If the fatal cases which developed within a fortnight after the end of treatment, and in which there is reason to believe that the inception of treatment was too late, be excluded, the mortality for 1886 falls to 0.93 per cent.; for 1887 to 0.67 per cent.; and for 1888 to 0.55 per cent.

Dr. Welch considered the various objections which have been made to Pasteur's method and to the value of his statistics. Some of these objections are of a purely hypothetical nature. Much force has been attached to von Frisch's experiments, which seemed to some to invalidate the scientific basis of Pasteur's method of treatment. Von Frisch claimed that it is impossible to render animals immune after the reception of the virus of rabies in a manner certain to produce the disease. In opposition to von Frisch it has been demonstrated by Pasteur and others that, in a large proportion of cases, the development of rabies may be prevented in dogs which have been inoculated beneath the dura mater with the strongest virus. The treatment, however, must not be deferred under these circumstances later than the second day, and must be by the intensive vaccinations. Bardach succeeded in this way in saving 60 per cent. of the dogs inoculated beneath the dura mater. This test is evidently the most severe one to which Pasteur's preventive treatment can be subjected, one far more severe than is required to meet the ordinary channels of infection with rabies. It must be admitted, therefore, that Pasteur's treatment rests upon a satisfactory experimental basis.

The criticisms raised against drawing favorable conclusions from the large mass of statistics published by Pasteur have been many, but the most important are that we are ignorant of the mortality following the bites of rabid animals, and that there are included in Pasteur's statistics an indeterminate number of persons bitten by animals not rabid. As regards the first point, there are various careful collections of statistics which show an average mortality of about 15 per cent. (Labbanc, Dujardin-Beaumetz, Horsley). All admit that bites by rabid animals on the head and face furnish a much higher mortality than this; it

being given as 88 per cent. by Brouardel. To meet the second criticism, Pasteur's statistics, which are published monthly, are arranged in tables which embrace: *a*, persons bitten by animals proven experimentally to be rabid; *b*, cases in which the existence of rabies is certified by a veterinarian; *c*, cases in which there is reason to suspect rabies in the animal. Pasteur's statistics for class A, that is for persons bitten by animals proven experimentally to be rabid, for the years 1886, 1887 and the first half of 1888, yield a mortality from rabies of 1.36 per cent.; or, if those who died within a fortnight after treatment be excluded, of 1.09 per cent.

Dr. Welch collected from Pasteur's reports for the first half of 1888 those bitten on the head and face by animals proven experimentally to be rabid. There were 59 cases, with 4 deaths from rabies during treatment and 2 following treatment. Of the latter 1 was seized three days after the cessation of treatment, and it is reasonable to suppose that in this case the treatment was begun too late. If this case and those dying during treatment be excluded, there remain 54 cases with 1 death, a mortality of 1.85 per cent.

In view of the universally conceded high death rate following bites on the head and face by rabid animals, this result leaves no room for doubt as to the efficiency of Pasteur's treatment, although it is not unfailing.

It is a sufficient answer to the assertion that has been made that Pasteur's intensive inoculations are dangerous in that they may actually produce the disease, that the mortality from rabies is strikingly smaller after the application of the intensive method than after the simple treatment.

SUCCESSFUL CASE OF NEPHRORRAPHY FOR FLOATING KIDNEY.

Read before the Philadelphia County Medical Society, March 27, 1889

BY W. W. KEEN, M.D.,

PROFESSOR OF SURGERY IN THE WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA.

Miss E. J. F., of Sunbury, Pa., æt. 35, height four feet eleven inches, weight ninety-two pounds, was sent to the Woman's Hospital on October 4, 1888, by Dr. Mary A. McCay, with a diagnosis of floating kidney. For the following notes I am indebted to Dr. Chapin and Dr. McKee, resident physicians. The patient was delicate as a child; menstruation began at 15, and was always painful and irregular. At 18 years of age she was thrown from a wagon, falling forward with considerable force on her chest and abdomen. Shortly after the fall she suffered with severe pain in the right side and a great deal of distress across the back. Menstruation ceased for six months, and was followed by dropsy and severe illness. There was frequent inclination to vomit,

and a great deal of palpitation of the heart. In spite of constant medical attention, she dragged out a miserable existence. About seven years after the fall she noticed a movable tumor in the abdomen, which Dr. McCay believed to be a floating kidney.

Present condition.—Appetite and sleep poor; urine 1020, slightly alkaline, twenty-nine ounces in twenty-four hours, no albumen, no sugar. Heart and lungs normal; uterus retroflexed. In the right abdomen was a tumor, about the size of the kidney, which could be freely and easily pushed two or three inches to the left of the middle line back into the right lumbar region, or down into the right iliac fossa. Neither the hilum nor the blood-vessels could be distinctly made out. Percussion over the position of the right kidney showed a tympanitic note, the left renal dulness being distinct and normal. The tumor was evidently not connected with the uterus, ovary, or liver.

Operation, October 26, 1888.—Ether was administered. An oblique incision was made at the outer border of the quadratus lumborum four inches long. As soon as the abdominal fat was discovered, search was made for the kidney. The colon was first found, but the kidney was absent from its normal position. Strong pressure being made on the abdominal tumor, it was partly pushed back into position, but could even then only be touched by the finger tip. On separating the borders of the incision by retractors, it was seen to be the kidney, bare of all fat. In order to replace it entirely, it had to be seized by a volsella. Seven carbolized silk sutures were next introduced by a Hagedorn needle, four posteriorly and three anteriorly, through the capsule and substance of the kidney, by which it was attached to the muscles and aponeurosis of the abdominal wall. Seven deep sutures of chromicized catgut were then introduced through the entire muscular wall of the loin, but they were not tied, as I intended that the wound should remain open for a few days, if not permanently, in order to produce cicatricial tissue between the kidney and the muscular wall. No provision for drainage was necessary of course. The wound was covered with an ample bichloride gauze dressing. Her recovery was entirely uneventful. Her highest temperature was 100.9°. The urine was entirely free from any blood, though the bladder was irritable, and the catheter had to be used for several days. The wound was so completely filled up within the first forty-eight hours, that I removed the stitches that had been passed through the muscular wall. I kept her flat on her back for four weeks, when she was allowed to rise for a short time. There was considerable, apparently rheumatic, pain in the small of the back for three or four weeks after the operation, which disappeared and again reappeared,

and which seemed to be benefited by salol. Seven weeks after the operation there was a moderate amount of albumin in the urine, which disappeared after the use of Basham's mixture for three weeks. Soon after she got out of bed, I tried the effect of a pad to support the kidney in front, but its use caused so much discomfort that I abandoned it, trusting wholly to the silk sutures and cicatricial tissue to hold the kidney in place. The tumor formerly discovered in the abdomen was entirely gone, and the normal renal dulness reestablished, though a little lower down. She went home on the 5th of January, 1889. I heard from her to-day, March 16, 1889, and she says: "My back is still weak, but the pain is fast disappearing. The kidney is still firmly anchored, and I am feeling better generally. Words cannot express my gratitude to you for what you have done for me."

REMARKS. *First, the cause.*—A lax abdomen following frequent pregnancies has been supposed to be the origin of floating kidney, as it is of floating liver. In the case here narrated, the patient was unmarried, and the abdominal wall was not at all lax. Again, the absorption of the perinephritic fat has also been supposed to be a cause, but in this case as soon as the abdominal wall was penetrated, the perinephritic fat was at once encountered. But it was a noticeable fact that the kidney itself was entirely free from any fat. In other words, the fatty bed in which the kidney should lie was in its proper place, but the kidney was displaced and there was no fat on the kidney itself. It seems reasonable to conclude that the dislocation of the kidney was due to the fall at the age of 18, though the abdominal tumor was not discovered till seven years later. Landau, who has written the best monograph both upon floating kidney and floating liver, states that of 314 cases of floating kidney, 273 were in women as against 41 in men. In 178 cases, it existed on the right side in 151, on the left in 13, and in 14 on both sides. The present case being in a woman, and upon the right side, emphasizes still further his statistics.

Secondly, the symptoms.—Digestive disturbances, especially constipation and very fetid breath, were not marked, though they were present to a moderate degree. The chief trouble was pain and constant discomfort, which was not only physical, but mental, the very existence of the tumor being a source of constant worry. The tumor itself was not especially tender to the touch, but it created a constant aching pain. Neither the hilum nor the pulsating renal artery could be distinctly made out, but the character of the tumor and the altered renal dulness made the diagnosis quite clear.

Thirdly, the treatment.—Recumbency alone has been advised by Landau, but this seems to me altogether too expectant. Only the most sanguine

could believe that by this treatment, if such it can be called, a kidney would resume its normal position and quietly continue there sufficiently long for the adhesions to be reestablished with any prospect of permanency.

I did not try any treatment by pad or bandage, as the patient was from a distance and could not remain the long time necessary to decide whether such palliative treatment would answer. On the other hand, extirpation of the organ was equally foreign from my thoughts. In my opinion, this should only be done after failure of an attempt at fixation. The danger to life of a floating kidney is absolutely *nil*. It is, therefore, only to remedy the discomfort that exists that we operate. Hence, I do not think extirpation at all justifiable unless we first attempt to fix it *in situ*, and having so failed, it is only justifiable even then in case the discomfort is very great. Dr. Maurice H. Richardson (*Boston Medical and Surgical Journal*, June 14, 1888), who has published an excellent paper with a full bibliography, quotes from Brodeur the following figures: Of 235 nephrectomies, 125 were done by lumbar incision, with 47 deaths (37.6 per cent.), 110 by abdominal incision, with 55 deaths (50 per cent.). As against this large mortality from nephrectomy, however, Gross has collected 17 cases of nephrorraphy, with only one death, a mortality of only 6 per cent. It should be added also, that in the fatal case (Ceccherelli, *Centralbl. für Chir.*, 1884, 44, 743) the surgeon passed the stitches around the twelfth rib, a procedure which is absolutely needless as well as dangerous.

Hahn (*Centralbl. f. Chir.*, 1881, p. 449) first proposed fixation for a floating kidney, by operative procedure, and practically perfected the operation. The operation is simple. The patient being laid upon the side, an oblique incision is made at the outer border of the quadratus lumborum. The edge of this muscle being recognized, the perinephritic fat is found immediately in front of it, at its outer border. This fat having been cut or torn through, the kidney may be seen at once, but, if it is very movable, it may be so far displaced as not to be seen, or, as in the present case, may be even felt with difficulty by the tip of the finger, even when an assistant pressed it firmly back through the abdominal wall.

Mr. H. Morris (*Surgical Diseases of the Kidney*, p. 45) makes a distinction between a kidney which has no mesonephron, but moves about freely behind the peritoneum, this being called "movable kidney," and a "floating kidney" which does possess a mesonephron, and therefore floats freely in the peritoneal cavity. In cases, therefore, of a strictly floating kidney, it would be necessary to open the peritoneal cavity before it could be fixed in the loin. This distinction is confirmed by the four cases of dissection to which

Morris refers. Comparing them with the present one, the range of movement to the left of the umbilicus and into the right iliac fossa was so great in this case, that it would seem proper to call it a "floating kidney," yet, at the operation, no renal mesentery or mesonephron was found. The probable mode of its production would also militate against the existence of any mesonephron. The kidney was far away from its normal position, but when pushed back into its proper place no layer of the peritoneum could be found that by any possibility could be called a mesonephron, and the peritoneum was certainly not opened.

In spite of the fact that Paoli (*Centralbl. f. Chir.*, 1885, 51, 910) cut through the twelfth rib in order to obtain room, it would seem to be rarely necessary to do so. When found and pressed back, the kidney should be fixed as nearly as possible in its normal position. Usually it will be impossible to replace it as high as it was at first, but lowering the site by two inches is not uncommon and seems to be of no importance.

The sutures that have been employed (either of silk or of catgut, disinfected, of course) may be passed (1) through the capsule of the kidney, or (2) through the parenchyma and capsule both, and may either be (3) left permanently or (4) removed. In this case I employed antiseptic silk, which I consider decidedly the best, and passed the stitches not only through the capsule, but through the parenchyma of the organ itself, three on the anterior surface and four on the posterior, stitching the kidney to the muscles, and what I consider more important, to the aponeurosis, which exists on each side of the incision. Finally, these stitches were not removed, but were left *in situ*. I believe with Svernnson (*Centralbl. f. Chir.*, 1886, 824), that many failures have been due to employing absorbable catgut, to the avoidance of passing the stitches through the substance of the kidney, and to removal of the stitches, which in all cases I think should be left in, whatever the material employed. Svernnson inserted as many as fourteen silk stitches, which were left in place and caused no trouble. The wound is best left to heal by granulation. I introduced a number of stitches to close the abdominal wall if necessary, but in twenty-four hours it was so filled up that it was evidently a needless precaution. The larger amount of cicatricial tissue that is produced by leaving the wound to heal by granulation probably fixes the kidney more firmly.

Another very important point is, that the patient should lie flat on the back for at least a month after the operation, in order that the cicatricial tissue binding it in place may become thoroughly developed and firmly established. Even then, I would advise some support for the kidney in front by a pad or bandage, provided

the patient bears it well. In this case I soon abandoned it, as it caused too much discomfort. It is to be noticed that though the stitches were passed through the kidney substance, the patient had no hæmaturia (this was carefully watched for) and that no inflammation or reaction seemed to follow. But seven weeks after the operation considerable pain developed in the region of the kidney together with some albuminuria. This disappeared, however, after the use of Basham's mixture. The pain seemed to be rheumatic, and was soon relieved by the administration of salol.

A CASE OF NEPHROTOMY.

Read before the Philadelphia County Medical Society, March 27, 1889.

BY L. W. STEINBACH, M.D.,
OF PHILADELPHIA.

On July 17, 1888, Mrs. Anna H., 44 years old, from New Jersey, was sent by her attending physician to my department at the Polyclinic with a statement that she had been under his care for about a month, that she presented symptoms of hepatic and gastric disorders which brought about anæmia, nervousness and irritability of the heart. She complained of indigestion, frequent vomiting of food or of mucus, attacks of palpitation of the heart, and loss of flesh. One week ago his attention was directed to an induration in the right hypochondriac region, and, deeming it of serious import, he referred the patient to our clinic.

From her own statements and those of accompanying friends we gathered, in addition to the above, the following history :

Mrs. H. was formerly a hard working country woman, who bore six healthy children, but had had no miscarriages. She suffered in several of her confinements with puerperal mania, but considered herself in good health until eleven years ago, when, she thought, she became dyspeptic. Five years ago she noticed a lump in her abdomen, of which she made no mention to anyone until one month ago, up to which time she was able to attend to her household duties. She complains of headaches and constipation, and has not noticed any sediment in or discoloration of the urine, nor could she recall having suffered with pain that would indicate the passage of a biliary or renal calculus. Her pulse, respiration and temperature are normal, she looks anæmic, the complexion is muddy, her conversation and behavior indicate the existence of some mental weakness, the body is emaciated. Inspection shows a prominence in the right lumbar region, whilst percussion and palpitation reveal the presence of a tumor extending from the lower border of the ribs vertically for about seven inches, and, laterally, occupying the centre of the lumbar region to the extent of three inches. The percus-

sion dulness is continuous with that of the right lobe of the liver. The tumor is freely moveable below, and felt through the abdominal walls imparts the sensation of a bag filled with small pebbles. Believing that the case before me was one of a gall-bladder filled with calculi, and fearing lest manipulation would cause rupture of the cyst, I desisted from further palpation and directed my inquiries toward finding other symptoms of biliary obstruction. I drew off the urine with a catheter and submitted it to a chemical analysis, which showed the absence of albumen and the presence of some bile-pigment. No particulars of the nature of the stools could be obtained. In a letter directed to her physician, I gave it as my opinion that the patient was suffering from the effects of an enormously distended gall-bladder filled with calculi, and recommended a cholecystotomy.

One week later, she returned with the consent of her physician ready to undergo the proposed operation. After a preparatory treatment by baths, a laxative and rest in bed for two days, and after a consultation with my assistants and the physicians composing my class, in which the existing symptoms, and especially the absence of pronounced jaundice, were separately and carefully considered, I believe there was no more reserve in the minds of these gentlemen than in my own that the former diagnosis was the correct one. Dr. Keen also hastily examined the patient, concurred in the diagnosis and lent his kind assistance in the operation.

On July 26, the patient being anæsthetized with ether, an incision three inches in length was made in the right linea semilunaris, over the most prominent portion of the tumor, beginning at the border of the ribs and dividing the abdominal muscles and peritoneum ; the apex of the tumor was reached without encountering any of the abdominal viscera. The calculi could now necessarily be felt more distinctly than before the division of the abdominal wall, and, meeting with difficulty to place the tumor on the trough-shaped apparatus devised by Dr. Keen, it was decided to pick up a fold of the cyst between two pairs of hæmostatic forceps and make an incision between the forceps, so that the calculi might be removed without permitting the escape of bile or mucus into the peritoneal cavity ; this was accordingly done, and a few pieces of calculus removed, which, however, did not correspond in shape, color and general appearance to calculi of biliary origin, especially when the forceps grasped a stone evidently of large size and immovably fixed.

The idea of impacted gallstones was dispelled by the appearance of these calculi, and the thought that flashed upon the mind of every one was, that the tumor was a kidney.

The fear of rupturing the normal gall-bladder

having suddenly vanished, the lips of the abdominal incision were drawn apart more freely, which brought to view the margin of the right lobe of the liver and a normal gall-bladder in its normal position.

Further examination showed the tumor to be the right kidney distended by several calculi of different shapes and sizes. The organ itself was twisted by being turned upon its vertical axis from behind forward and to the left, and upon its horizontal axis from above downward and from behind forward, so that the dorsal surface and the upper end presented at the anterior abdominal wall.

It was now at once decided to remove the kidney, a superficial examination indicating the existence of a kidney on the left side. The pedicle of the tumor, consisting of ureter, artery and vein, was ligated *en masse* with a silk cord, the kidney cut off, the abdominal incision closed with sutures and dressed. The patient was put to bed, and after half an hour came out from under the influence of the anæsthetic and inquired of the nurse about the particulars of the operation. She gave no evidence of pain or suffering, and assumed her usual air of indifference to her surroundings which, according to the statement of her niece, was her peculiarity. Three hours after the operation the bladder was catheterized, but no urine obtained. Catheterization was repeated at intervals of six hours during the two succeeding days with a like result. The temperature at 8 o'clock p. m., six hours after the operation, was 101° F., falling to 99° on the following morning, gradually rising to 103° towards evening, and falling in the same manner to 100° on the morning of July 28. She slept for a few hours during the night after the operation, and after a small dose of morphia; took moderate amounts of nourishment and some stimulants. About noon of the third day began to complain of soreness all over the body, became irritable and restless, but continued to take milk and whisky. She passed no urine up to the time of her death, which occurred at 6:20 p. m., fifty-four hours after the operation, caused by suppression of urine. A post-mortem examination was not held.

The removed kidney with the calculi weighed fourteen and a half ounces, and is among the pathological specimens which Dr. Keen presents this evening.

In submitting the case for discussion and criticism of the society, without explanations in justification of the course of which I have pursued, I am adding one to the great number of recorded and unrecorded cases of movable kidney, the removal of which has been attempted or accomplished in the belief that the tumor was ovarian, uterine, splenic, or belonging to any of the abdominal or pelvic organs.

A CASE OF LAPAROTOMY FOR EXTRA-UTERINE PREGNANCY.

*A Paper read at the Allegheny County Medical Society,
March 16, 1889.*

BY N. O. WERDER, M.D.,
OF PITTSBURGH, PA.

At the November meeting of this Society I reported a case of extra-uterine pregnancy in which I had performed abdominal section with a successful result. To-day I present the specimen of my second case of tubal pregnancy, removed by laparotomy, on February 14th, of this year.

The history of this case is, briefly, as follows:

Mrs. M., 27 years of age, married, two children, the youngest 16 months old, has been suffering with periodical attacks of severe abdominal pains for almost a year, for which she several times required medical treatment. During the five or six weeks preceding the operation these attacks increased in frequency and severity, making her unfit to do her ordinary household duties. Walking almost always produced a great deal of suffering. On January 26th, of this year, I was consulted for one of these attacks of pain, which was referred to the pelvic region, principally the left side. Making a vaginal examination, I found the uterus enlarged to the size almost of a two months' pregnancy, and to the left of this, in the region of the left tube, a soft, extremely tender mass, which was slightly movable. A careful bimanual examination could not be made on account of the very great sensitiveness of these parts. She had menstruated regularly every four weeks during the last eight or nine months, and was at this time still nursing her baby. At the two subsequent examinations I found no change in her condition, except, perhaps, that this tumor was slightly larger than before. The diagnosis was not quite clear, but I was inclined to the opinion that it was either a hydrosalpinx, or a pyosalpinx, more probably the latter. As her suffering at times had almost become unbearable, I advised laparotomy, to which she readily consented, but the operation was deferred until after her next menstrual period, which was now very close at hand. Menses lasted five days, and presented nothing unusual. In the afternoon of the 13th of February, the day preceding the operation, she came to my office in a carriage, from her home, for the purpose of going to Mercy Hospital. On examination I found her condition unchanged; the mass, however, seemed now decidedly larger. The riding on the rough country road from her home did not seem to have caused her as much suffering as expected, and she was cheerful and feeling better than for several days previously. But on her way to the hospital the pains returned in unusual severity, and she arrived there faint and nearly collapsed. Several hypodermic injections of morphia made

her more comfortable, but she continued very sick and sore all night. On my morning visit, before the operation, she looked very pale, and was very feeble, still suffering considerable pain. Vaginal examination was not made.

On opening the peritoneal cavity dark blood escaped from the wound, and the abdomen was found containing a considerable quantity of blood, liquid and coagulated. In reaching down for the sac, on the left of the uterus, I felt a small rent in it, probably $\frac{1}{2}$ inch long, which, however, in trying to bring it to the surface, was enlarged, so that all its contents escaped into the abdominal cavity. The bleeding was now very free, the blood being bright red, and easily distinguishable from the old dark blood already contained in the abdomen. The sac was now tied off, and the clots contained within the pelvic cavity turned out. After washing out the abdomen with hot distilled water it was closed, leaving, however, a glass drainage tube. Blood continued to discharge from this tube for three days, when it was removed.

The patient rallied very nicely from the operation, and made an uninterrupted recovery, her temperature and pulse remaining perfectly normal after the fourth day. She left the hospital on the 21st day, and is now in good health.

Rupture of the tube must have taken place on her way to or at the hospital, probably as a consequence of the jolting of the carriage. This evidently was the cause of the faintness and slight collapse after her arrival at the hospital the evening before the operation.

Comparing the histories of the two cases operated on by me, we find the first case an almost typical one of ectopic pregnancy, and one of comparatively easy diagnosis to one at all familiar with this interesting anomaly, while the second case is as atypical as possible, in which I claim a diagnosis to have been entirely impossible, for there was not the slightest reason to even suspect a pregnancy, as the patient had been menstruating regularly, her last catamenial period terminating just a few days before the operation, and she was still nursing her baby at the time she came under observation.

This case illustrates again the great difficulties in diagnosing extra-uterine pregnancy, and I cannot agree with Hanks, when he states that the diagnosis can be made in at least 95 per cent. of cases. The case also demonstrates that this interesting affection is by no means such a very rare condition as some seem to suppose, as this is the second case occurring in my own practice within the period of four months. That this was a case of tubal pregnancy there could be very little doubt, but in order to be perfectly certain I sent the specimen to Dr. Wm. H. Welch, of Johns Hopkins University, Baltimore, for examination, and he verified the diagnosis. The specimen, he

states, consists of an ovary, part of a Fallopian tube, the intervening broad ligament, the fetal membrane and a placenta with umbilical cord.

REPORTS FROM HOSPITALS.

SURGICAL CLINICS AT THE WESTERN PENNSYLVANIA HOSPITAL BEFORE THE STUDENTS OF THE WESTERN PENNSYLVANIA MEDICAL COLLEGE.

BY PROFESSOR J. B. MURDOCH,

SURGEON TO THE WESTERN PENNSYLVANIA HOSPITAL AND PROFESSOR OF CLINICAL SURGERY IN THE WESTERN PENNSYLVANIA MEDICAL COLLEGE.

[Reported by WILL. N. PRINGLE, M.D., a member of the Graduating Class.]

November 27, 1888.

As we are now studying the subject of fractures I embrace every opportunity to illustrate the different fractures of the bones of the human body to you.

FRACTURE OF THE LEFT LEG AND RIGHT THIGH.

The man we show you now is a railroad employé; yesterday while standing on a carload of gravel that was being pushed ahead of the engine, he suddenly became aware that the car was off the track; he signaled the engineer and endeavored to get the train stopped, but before he could do so the car went over an embankment, throwing him and the dirt down the hill. Just before going over the bank, however, he jumped, alighting on his toes, he says. He has sustained a fracture of the left leg and right thigh, and has a wound over the right patella. Whether he received these injuries from jumping, or from being thrown, he does not know; they were at all events probably caused by indirect violence. As he lies before you the first thing you will notice is that his right leg is everted. You also see some swelling. By measuring I find a little shortening of the right leg. He is unable to raise his heel from the table, and as I manipulate the limb I find a false point of motion about the middle of the thigh, so we have nearly all the symptoms of fracture of femur in history of the accident, deformity, swelling, pain, loss of function, false point of motion, but we have no crepitus. This is absent, possibly because the ends of the bone have overlapped or slipped past each other. This is often the case. We have abundant symptoms, however, on which to base a diagnosis of fracture, even if we do not elicit crepitus. We have made strong extension, but failed to bring the two ends together, but for all that it does not follow that they cannot be brought together, for although we may have ap-

plied extension to the amount of a hundred pounds and failed, still by *continuous application* of only eight or ten pounds for thirty-six or forty-eight hours, we may bring these fractured extremities into exact apposition. We do not, however, as a general thing, in a man of this age, expect so good a result as we would in a child, but are usually satisfied if we get strong union with a little shortening. This right leg was dressed with weight and pulley, and Hamilton's splint, which extends from the axilla to the sole of the foot, with a small piece extending out at right angles about six inches from the side of the splint; this is to prevent eversion, or rolling out, or rotatory deformity of the limb. By a bandage around the upper end of the splint and around the body of the patient he is prevented from rising, thus securing quiet and rest. The left leg you see is also broken below the knee, and by the amount of motion we know that both bones are broken. Here, too, we are able to secure almost all of the symptoms of fracture, including crepitus. Shortening, however, is absent, but when both limbs are fractured we have no fixed point from which to calculate, hence shortening becomes of no value as a symptom in this form of fracture. Over the spine of the tibia you see quite a large bleb. Where you find these you must expect to find a low state of vitality and an impaired nutrition; and you must be very careful about applying tight dressings or bandages, or you will surely have gangrene in the extremity of the limb. A question might arise in regard to the treatment of these blebs. Some surgeons recommend that they be opened at once. I never open them. I think that the cuticle heals better under the epidermis than it would do if it were opened and evacuated. My usual mode of treating fractures of this kind will be practiced in this case. The leg will be kept in the fracture box for a week or ten days, and then a plaster dressing put on.

A COMPOUND FRACTURE.

I will next show you the compound fracture which you saw us dress two weeks ago. We have failed to get these fragments to unite, and have been unable to bring them into apposition; there is either a tendon, muscle or piece of bone in the wound preventing union. I propose, to-day, to cut down on these fragments and saw off the ends of the broken fragments, bring them into close apposition and wire them together. Then by diet, regimen and good constitutional treatment generally, we hope to get union and repair here. You see the bone protruding through the skin, and entirely denuded of periosteum; this I will saw off. I have tried so often to impress upon you the dangers from compound fractures as compared with simple fractures, that I say now, that if you are ever able, by the use of lint

soaked in compound tincture of benzoin, collodion or in the patient's blood, to convert a compound into a simple fracture, you have saved your patient much suffering and loss of time, and perhaps his life. But you will often meet with cases like this where you will have trouble in doing this, and you will also meet with other cases in which you will fail entirely.

In all operations on bones I think it a good plan to use an Esmarch bandage. I think it is more useful to the surgeon in these cases even than it is in amputations, but in compound fractures and in injuries where the vitality is low I never like to use it. I am always afraid to do anything that might interfere with the blood vessels leading to the part, and for that reason I would rather lose a little blood than to risk injury to the already devitalized vessels that must carry the material for the repair of the wound. By removing the fractured ends of this tibia I have been able to bring them into apposition, and now, for fear of having bowing of the limb, I will saw out a short section from the fibula. The limb will now be dressed in the usual way, and we will hope for the best for this man, although his limb is by no means yet saved.

December 1, 1888.

FRACTURE OF THE VERTEBRÆ.

The first case I will bring before you to-day is one of those cases of which we see too many in this hospital every year, namely, fracture of one or more of the vertebræ. These cases are, in my mind, the most melancholy of all the cases we have to witness, and they appeal to the sympathy of every man of any feeling at all. If they were crushed and killed outright they would not, it seems to me, present half so sad a picture as they do in cases like this, with the lower part of the body practically dead and the upper part alive and well. They lie on their back, usually, until large bed sores form on their body and they die of exhaustion. This man was a coal miner, and while at his work in the mine, two or three weeks ago, a quantity of slate fell on him, crushing him to the ground and fracturing the vertebræ in the lower dorsal or upper lumbar region. This is the manner in which a great many of these injuries happen. This man also received at the same time a fracture of both bones of the leg three inches below the knee. These injuries of the spinal cord are somewhat allied to injuries of the brain, in so far as paralysis is concerned, although we do not have loss of consciousness, delirium and many of the other symptoms of compression of the brain. He has complete paralysis in his lower extremities, with incontinence of urine and feces. In cases of this kind there is usually, for the first day or two, retention, followed by incontinence of urine. This was the case in this man. He has all the power in his

upper extremities he has ever had, he can roll his head about, flourish his hands and arms in the air, and almost raise himself to the sitting posture, but he is as powerless to raise a foot from the bed as though his two legs were separated from his body. He is also unable to feel me pinch his legs or prick him with a pin. He has paralysis of both motion and sensation. As we turn the man over you see two large bed sores almost covering his entire buttocks, which have formed in the short space of three weeks. When you have a patient that you know must lie in bed for a long time, much benefit may be derived from washing the parts with alcohol every day. Some recommend alum water. This may be done before the ulcers form, but after the ulcers have formed the best thing you can do is to cover them with moleskin plasters or chamois leather, which may be spread with Peruvian balsam.

Now, while these kind of cases almost invariably die, there are exceptions to the rule. There was a man in the wards here about a year ago with just such a fracture as this, except that the deformity was more marked, and he had neither paralysis of motion or sensation, and in three weeks we put a plaster jacket on him and he soon after left the hospital alive and well. The only explanation in this case was that, although there was considerable deformity, it was not in the direction to make pressure on the cord. There are various treatments for these fractures, one of which is by extension and counter-extension, and this I think would have been good treatment in this man's case had it been resorted to early enough. Another mode of treatment is that of cutting down on the vertebræ and elevating the fractured portions, much the same as you would trephine the skull for pressure on the brain.

TREATMENT OF COLD ABSCESSSES.

We have another case to show you to-day, a man with two swellings on his back. His family history is of the best. About one year ago he received a blow on his back over the site of the upper swelling, and eight months ago he had pneumonia, for which his physician painted his back with some substance, after which these swellings appeared. He had them aspirated and a pint of pus withdrawn. After this they again filled up, and I can now readily detect fluctuation, and as I press firmly on the upper swelling the fluid is all pressed out and distends the lower tumor, and I can then press it from the lower back into the upper tumor, so you see they communicate with each other. This is known as a cold abscess, and the contents of a cold abscess differ somewhat from the contents of an acute abscess, that from the latter being thicker in consistency, or creamy and more like normal pus, while that from the chronic form is more fluid or liquefied. In children this matter is likely to form near the

vertebral column, and following the course of the psoas muscle point in the groin. A very superior manner of treatment of cold abscess, in my mind, is that invented by a German surgeon, namely, to evacuate the abscess thoroughly, by means of the aspirator or trocar and canula, then inject into it an ethereal solution of iodoform. The ether evaporates, or diffuses, through the cavity, carrying the iodoform into every pocket, sinus and crevice in the cavity, thus acting as a most thorough antiseptic. This is the treatment I propose to give this case. In passing the trocar I select the most dependent point, because it is here that I am most certain to empty the cavity most thoroughly. This is a good rule to which there are many exceptions, however. In many abscesses you would have to go through a great mass of tissue, in order to open it at the lowest point. In these cases I would advise you to open at the thinnest point, or at the point where nature would, unaided, have made an opening. I will inject two ounces of the ethereal solution of iodoform into this cavity. It will then be left undisturbed for a few days, unless the temperature goes up, or other indications present themselves, showing that all is not doing well. If the temperature goes above 100° I will at once open the entire cavity freely, scrape it out with a Volkmann spoon and drain it thoroughly, and treat it as an acute abscess.

MEDICAL PROGRESS.

DIFFUSE CALCIFICATION OF THE LIVER.—At the meeting of the Pathological Society of London on April 16, Mr. TARGETT showed a specimen of diffuse calcification of the liver, which was removed from a man æt. 62, who died in the Exeter Hospital. It was presented to Guy's Hospital Museum by Dr. Davy. There had been a tumor in the epigastric region for seventeen years, which was very hard but not tender, and did not interfere with his work as a farm laborer. Four months before death he developed an empyema on the right side, for which he was treated in the hospital. At that time the abdomen presented a swelling of stony hardness in the epigastric region, which moved with respiration, and appeared connected with the liver. There was no ascites, but the veins over the upper part of the abdomen and the lower part of the chest were enlarged and varicose. There was no jaundice until two days before death, which resulted from facial erysipelas. The clinical report was very incomplete, and the condition of urine was not mentioned; but at the post-mortem examination the kidneys looked normal, though much enlarged. The spleen was

four or five times its usual size. The liver was firmly adherent to all the surrounding parts; after removal it weighed 66 ozs. The left lobe was very much enlarged, and was the cause of the epigastric swelling. The capsule was much thickened, and the substance of the liver so hard that it had to be sawn into sections. The greater portion of the organ was then found to be replaced by fibrous tissue, which was infiltrated with calcareous deposits, composed of carbonate and phosphate of lime and a large proportion of organic matter, but did not contain cholesterol or bile acids. Microscopic examination of the least affected parts of the liver showed changes like those of monolobular cirrhosis, and there were many groups of small round cells in the strands of fibrous tissue. One striking point was the amount of new tissue in the centre of the lobules spreading out between the rows of liver cells. The other parts of the liver were decalcified and examined, but they showed little more than fibroid tissue. There was no caseation; no gummata or evidence of parasites could be found. He considered that the thickening of the capsule, together with the amount of fibrous tissue in the interior of the organ, were suggestive of the primary change being syphilitic, but there was none of the cicatricial contraction so commonly found in old syphilitic livers. The clinical history did not mention syphilis or alcoholism. The specimen was referred to the Morbid Growths Committee. — *The Lancet*, April 20, 1889.

INTRACELLULAR DIGESTION.—(*Annales de l'Institut Pasteur*, 1889, No. 1.) As most protozoa and phagocytes, because of their smallness, are not well adapted for a microscopical observation of the course of intracellular digestion, Metschnikoff made his observations first on myxomycetæ. The amœboid character of these organisms, their ability to receive carmine-granules, spores, etc., has already been proven by de Bary. The existence of a pepsin-like ferment in *æthaliu septicum* has been established by Krakenberg, and later on by Reinke and Greenwood. To be sure, it seems to be effective only in acid solutions, and for that reason—according to the two last-named authors—is of no benefit to the myxomycetæ themselves. Further difficulties in observing the myxomycetæ exists because of the constant movements of their protoplasm, and because sometimes the granules already taken up are thrown out again, etc. Nevertheless Metschnikoff succeeded in observing in plasmodium *physarum* a paling and all stages of solution of cells from the red sclerotium (of *phlebeomorphia rufa*). The granules of blue litmus powder intermingled with various plasmodii were not only taken up by the latter, but showed also, after a certain time, a decided rose coloring. If a volatile alkali was added or pressure with the cover-glass was made, the blue color of the litmus-

granules reappeared. Many of these granules were enclosed in smaller or larger vacuoli filled with a reddish, clear fluid; others seemed to be directly surrounded by the protoplasm.

Metschnikoff infers from these observations that the plasmodium of the myxomycetæ, although having an alkaline reaction, can produce an acidulous juice with a pepsin-like property to digest albuminous substances. Moreover, Metschnikoff convinced himself that digestion in acid media is not limited to myxomycetæ among lower organisms. The vacuoli fluid of *stylochnia* has a decidedly acid reaction on litmus; as has also that of *vorticella convallaria*, and Le Dantec recently established the same fact for the nutritive vacuoli of stentor polymorphus. There are also instances of digestive juices having neutral reaction in lower organisms; the author mentions several of these. But the main fact is this: that, in general, the method of digestion must be considered as diastatic.

Finally, the author made similar observations, which are not yet finished, upon the phagocytes of the higher animals. The tail of a larva of triton *tæniatus* was cut off and the surface of the wound rubbed with litmus powder. In a portion of the immigrated leucocytes the granules were subsequently found to be light-red. In osteoclasta Roustizky described, in 1874, an acid reaction of the cellular contents. There are many phagocytes in which no chemical reaction was found.—*Centralblatt für Bakteriologie und Parasitenkunde*, 1889, No. 15.

ON A PERMANENTLY SLOW PULSE AND ITS THERAPEUTIC INDICATIONS.—M. HUCHARD has repeatedly had occasion to observe and treat patients who presented the symptom known as a permanently slow pulse. He is convinced that this symptom originates, in a majority of cases, from a sclerosis of the arteries and in consequence of a genuine bulbar ischemia.

Often one cannot count more than from 28 to 30 beats a minute. Frequently the symptom is accompanied by dizziness, and even by epileptic attacks or attacks of syncope. Rarely the slow pulse occurs alone as a single symptom, but it is generally accompanied by attacks of varying character, all originating from sclerosis of the arteries. There are, in most cases, symptoms of cardiac accidents, and M. Huchard has been able to establish the fact that syncope is preceded by a characteristic retrosternal pressure, or even by angina pectoris. Slow pulse is often accompanied by various disorders related, like the latter, to sclerosis of the arteries; one may therefore, in watching the patients, see them become finally afflicted with cardiac troubles or with Bright's disease. Huchard thinks, however, that the name "permanent slow pulse" is defective, for the symptom is often only temporary; he would prefer to call

it "Stokes-Adams' disease," after the first authors who perfectly described these symptoms.

Not less interesting are the therapeutic conclusions. M. Huchard had an opportunity to observe a patient in whom the administration of sulphate of quinine, a vaso-constrictor, produced deplorable results. It is necessary to employ vaso-dilators, because we have to do with symptoms of bulbar ischæmia. This is the principal indication for the treatment. The iodide of potassium or of sodium may be resorted to, but M. Huchard prefers "trinitrine," which, like nitrite of amyl, is a congestant of the nervous centres. Of this he administers once or twice a day 3 drops of an alcoholic solution, 1:100; he makes use also of hypodermic injections, for which he employs the following formula: Water = 10 gr.; alcoholic solution of trinitrine 1:100 = 40 drops. One gram, or one Pravaz syringe-ful, contains 4 drops of trinitrine solution: one may make, therefore, from twice to four times a day, injections with $\frac{1}{4}$ of a syringe-ful.

From a therapeutic standpoint the degree of arterial tension must, therefore, be taken into consideration, which—though difficult to measure—can be estimated perhaps by an auscultation of the heart alone, with an accuracy sufficient for clinical purposes. If there is discovered at the aortic opening a diastolic accentuation of the second murmur, it may be safely supposed there exists an arterial hypertension; on the other hand, when there is lower tension, the second sound of the pulmonary orifice will be intensified. These indications are of great therapeutic importance. In the first period of arterial sclerosis of the heart, when the pressure in the arteries is too great, recourse must be had to vaso-dilators. When, on the other hand, the action of the heart becomes more feeble and the tension in the arteries diminishes, vaso-constrictors, and especially caffeine, should be used.—*La Semaine Médicale*, 1889, No. 14.

ANTIPIRYN IN THE TREATMENT OF DIABETES.

—A. ROBIN sums up the advantages of antipyrin in diabetes, according to his experience, as follows:

1. It may be employed from the outset in the treatment of diabetes where a glycosuria or acute polyuria is to be reduced without delay.

2. It allows of a suspension of the diet in patients who dislike the latter, without their losing the benefit of the previous restriction.

3. It is indicated when the diet, long continued and well tolerated, has produced its greatest effect in reducing the glycosuria and polyuria.

4. A wise combination of diet and antipyrin, associated in a sort of alternating manner, appears to be the best treatment for diabetes.

5. It is not necessary to continue the use of the drug if it does not produce an immediate and considerable diminution of the glycosuria.

6. One of the best ways of judging the effects of antipyrin is not only to ascertain every day the quantity of sugar in the urine, but also to measure daily the quantity of urine and its density. The action of antipyrin is favorable in the proportion in which the quantity diminishes and the density is reduced, or at least the latter should remain stationary. But if, with the quantity of urine diminishing, its density tends to increase, the use of antipyrin should be stopped immediately and permanently.

7. Albuminuria does not constitute an absolute contraindication. Its presence simply involves a question of its dose and of the duration of its use.

8. Finally, loss of appetite, emaciation, a sensation of weakness, pallor, oppression, swelling of the eyelids, or a sensation of tension in the face, are symptoms demonstrating, where they appear, that the use of the antipyrin is more harmful than useful, even if the glycosuria should be influenced favorably.—*La Semaine Médicale*, 1889, No. 15.

AMMONIACAL FERMENTATION OF URINE. —

The subject of ammoniacal fermentation of urine has recently been studied by Drs. A. RUSSO-GILIBERTI and G. DORRO in the Pathological Institute of Palermo, and they have published a note in the new monthly journal, *La Sicilia Medica*, concerning it. The discovery of Pasteur and Van Tiegheim, that in the alkaline fermentation of urine the transformation of urea into ammonia carbonate is correlative with the development of an organized vegetable ferment—the micrococcus ureæ—has now lost its original importance owing to the researches of Miquel and others, which have proved that this transformation is also brought about by the action of other microorganisms. Miquel describes as a factor in ammoniacal fermentation of urine a bacillus ureæ, very slender and mobile, occurring either alone or in groups of from two to four, which can transform urea into carbonate of ammonia almost as efficiently as the micrococcus ureæ; also an aspergillus, the action of which is less prompt. Leube's researches show other bacteria with the same capacity. He describes a sarcina and three species of bacilli, very different to the bacillus ureæ of Miquel, possessing the power of hydrating urea. In Flügge's Institute a micrococcus was obtained from fermented urine which also produces energetic fermentation of urea. It is distinct from Pasteur's, and as it liquefies gelatine it has received the name of micrococcus ureæ liquefaciens. Heraeus obtained four bacilli capable of producing hydration of urea; three liquefied gelatine, and were quite distinct from those described by Leube. It is thus seen that the micrococcus ureæ is not the only microorganism possessing this property. Warrington also, making further researches, found that the bacillus fluorescens had the power of trans-

forming urea into ammonia carbonate, and that certain species of bacteria do not possess that property. More recently, Drs. Russo-Giliberti and Dotto have made experiments with the penicillium glaucum, etc. They made a 2 per cent. solution of pure urea and poured 100 cubic centimetres of it into sterilized tubes; they then sterilized the solution according to Tyndall's method, keeping the tubes one hour a day, for seven days, at a temperature of 65° to 70° C.; one of the tubes was tested by the contents being added to water, which was then distilled and sterilized, no ammonia, nitric acid, nitrous acid or carbonic acid being found. In order to prove the absence of germs, the tubes were kept for ten days in the hot chamber at a temperature varying from 25° to 30° C. In one tube in which penicillium glaucum had been sown there was found an abundance of ammonia carbonate from the transformation of the urea. Consequently, this microbe must be added to the number of those which are capable of causing ammoniacal fermentation of urea.—*The Lancet*, April 20, 1889.

THE VALUE OF SULPHONAL IN THE INSOMNIA OF THE PSYCHOSES, though just now lauded by our German *confrères* and much employed by them, is not in our opinion the equal of chloral, especially if judiciously combined with a suitable bromide salt, like the bromide of ammonium or potassium. Occasionally a patient has returned to us after a trip abroad, and the almost invariable sulphonal prescription in case insomnia followed them there or overtook them while in Germany, and we have been better satisfied with the more complete night's rest and next day's mental tranquility and refreshment that followed the chloral than with that which succeeded the sulphonal. Nevertheless Dr. A. Cramer (*Berlin Klin. Wochenschr.*, 1888, No. 34.) has made experiments in his asylum on forty-five different patients suffering from melancholia, mania, paralysis, paranoia and hebephrenia, in all four hundred and seven experiments. In 92 per cent. sulphonal produced a sleep lasting five hours or longer; it came on in from one-quarter to one hour after the medicine was administered. The dose varied from 30 to 90 grains. The remedy appeared to act harmlessly and drowsiness did not persist long, save in exceptional instances after the patient awakened. The medicine was given at night, usually the most proper time, we may here remark, for the giving of a hypnotic draught.—*Alienist and Neurologist*, April, 1889.

IRRIGATION OF THE STOMACH IN VERY YOUNG CHILDREN.—FAUCHIER, who is the inventor of a tube for irrigation of the stomach, has applied it to children of the first period of life. This operation has long been practiced in Germany upon

children, and with good success. Irrigation of the stomach may be accomplished with the newborn almost as readily as with adults by the aid of a tube and funnel of suitable dimensions. The infant should be held with the head forward, so as to admit of the ready exit of matter which may flow back into the pharynx, the arms being secured under a napkin, which is tied around the neck. The author entirely disapproves of the plan of Ebstein, in keeping the child in the dorsal position while this operation is being performed. A case is narrated in which a child presented grave symptoms of gastro-intestinal disorder twenty-seven days after birth. The author washed out his stomach three times the first and the second days, and twice on the third day, the result being that the vomiting was soon arrested. The period of digestion, which at first lasted four hours, was gradually shortened, the child became quieter, the evacuations became regular, and a normal condition supervened. No medicine was given.—*Le Concours*, Dec. 15, 1888.

OSTEOTOMY FOR ANTERIOR CURVATURES OF THE LEG.—DR. DE FOREST WILLARD closes an interesting paper in the *Medical and Surgical Reporter* with the following conclusions: 1. Anterior tibial curves, during the soft and springy stages, may be corrected by manual rectification and the use of apparatus. 2. Braces are useless after hardening has occurred. 3. Manual fracture is the best and safest remedial operation in young children. 4. Instrumental fracture, or osteoclasis, is not as safe or effective as osteotomy. 5. Aseptic simple osteotomy, for all moderate degrees of curves, and cuneiform section for very severe grades, give almost uniformly good and speedy results, without suppuration. Subcutaneous operation by the saw is also a reliable operation. 6. Plaster of Paris is the simplest and most effective material for securing accurate position and maintaining absolute fixation.—*Gaillard's Medical Journal*, May, 1889.

ON THE PATHOGENIC ACTION OF MICROBES FOUND IN THE URINE OF ECLAMPTICS.—Two years ago E. BLANC made an investigation of this subject. Two rabbits were inoculated, one under the meninges, the other in the veins, with microbes isolated from the urine of an eclamptic patient. The former died with convulsions; the second had infectious nephritis. This year he repeated the experiments on rabbits, guinea-pigs, dogs and rats. The results justify the conclusion that there is in eclamptics a class of pathogenic microbes capable of producing convulsions, especially in pregnant female animals, as also special local symptoms.—*La Semaine Médicale*, 1889, No. 14.

SATURDAY, MAY 18, 1889.

ELECTRICITY IN GYNECOLOGY.

The above was the title of a paper read at the recent meeting of the Alabama Medical Association, by DR. W. E. B. DAVIS, of Birmingham. He believes that ultra-enthusiasm has led to frequent failure in the use of this remedy, but says there should be no question as to its importance as a therapeutic agent in gynecological practice when such men as Apostoli, the Keiths, Engelmann and other competent observers, who have had experience in its application, report most satisfactory results.

He advises the use of the current of the Edison circuit, direct from the dynamo, when it can be had, and thereby avoid the annoyances and inconveniences of a battery. Portable batteries have proved very disappointing for the administration of high intensities, and his work has been confined principally to office practice. Great stress is laid on the importance of the application of the faradic current in sub-involution of the uterus, and every woman who has had an abortion or is confined at full term, is placed on ergot, and should there be incomplete involution at the expiration of six weeks, he begins at once the use of the faradic current, with the bi-polar, intra-uterine excitor of Apostoli, and repeats the application every second or third day until the organ has returned to its normal size, "which can always be counted on with mathematical certainty." He does not recommend the use of the current immediately after every abortion or delivery as practiced by Apostoli, since this treat-

ment could not or would not be afforded, except by a very small class, unless it were certain that the uterus would not return to its proper size. For this reason ergot is prescribed by him in every case, as stated, since he thinks it acts very much as faradization on the smooth, non-striated muscular fibre of the uterus, although not by any means so prompt, energetic and reliable. All cases are examined at the expiration of six weeks to ascertain whether involution has been complete.

Cases are reported to show the value of the faradic current in sub-involution of the uterus, and to illustrate its efficacy in displacements due to the enlarged, hyperæmic condition of the uterus following parturition. The current of tension—the current from the long, fine wire—has proven a valuable agent for the relief of pain, and cases showing permanent relief were quoted.

The currents of quantity and tension have been used with very satisfactory results as indicated by Apostoli, but recently he has used the current of tension not only for pain, but to stimulate relaxed and enfeebled muscle fibre. The current of tension is borne better by the patient, and he has been unable to recognize the superior results of the current of quantity on muscle over the current of tension. In displacements of the uterus he supports the organ with wool tampons, and does not object to any form of pessary, properly fitted, in connection with the treatment by electricity. He believes that proper support of the organ, combined with the proper application of electricity, to be the most rational treatment for this condition.

When the uterus is enlarged not from subinvolution, but *hyperplasia*, he regards the continuous current as indicated. He says all cases of chronic endometritis are amenable to galvanism¹—the positive current when there is much leucorrhœa or profuse menstruation, and the negative in other cases. From 75 to 150 milliamperes are used twice weekly, for five minutes at a time. He does not say that electricity will do away entirely with such surgical procedures as shortening the round ligaments—Alexander's operation—or attaching the cornua of the organ to the abdominal wall, or the narrowing of the vagina by the many methods at present in vogue, but insists that many cases can be relieved by this method of treatment

¹ Apostoli. Chronic Metritis, etc.

which would otherwise be condemned to the knife.

He says the local application of the faradic current is capable of relieving many cases of amenorrhœa due to atrophy of the uterus. In menorrhagia, due to relaxation of muscle, to engorgement, when patient menstruates from eight to nine days, after a few applications the menstrual periods would only last from four to five days. The positive galvanic current is the remedy indicated for hæmorrhage due to a disease of the endometrium, and is the current usually indicated for hæmorrhage. Women often become pregnant soon after being treated by electricity, and it is unquestionably a valuable remedy for sterility due to nervous causes, so ably described by Dr. Campbell.

Neuralgic dysmenorrhœa and dysmenorrhœa in women of a hysterical temperament—whom the slightest excitement or worry will cause to suffer greatly—those cases where there is no apparent pathological lesion—he has succeeded, as with no other remedy, by the application of the current of tension or by the mild positive galvanic current. The negative current is indicated when the pain is due to mechanical causes in the cervical canal, and when there are inflammatory deposits around the ovaries, etc.

He said the subject which had concerned the profession most in connection with the use of electricity was *the treatment of fibroid tumors*, and the results of the treatment in the hands of Apostoli, the Keiths, Engelmann, Laphorn Smith and others, had demonstrated that this is *the treatment* for fibroid tumors which "offer probabilities of healthy retrograde metamorphosis."—Engelmann.

He had followed Apostoli's instructions in this class of neoplasms, and believed that the majority of cases could be symptomatically cured. Certainly Apostoli's treatment should be tried before resorting to hysterectomy.

HOT WATER IN ABDOMINAL SECTION.

At the recent meeting of the California State Medical Society, DR. BEVERLY McMONAGLE, Chairman of the Committee on Gynecology, read an interesting report on Pelvic Abscess and its Treatment by Abdominal Section. He mentioned one case in which "slight salivation followed the washing out of the abdominal cavity with a solu-

tion of bichloride 1:10,000." Since that occurrence he had used instead of antiseptic solutions in the abdominal cavity, pure water at a temperature varying from 110° to 120° F., but which had been thoroughly boiled. In the discussion that followed the reading of the report, Dr. H. W. Smith, of Placerville, said he had done some work in abdominal surgery; "and in using a 1:1,000 sublimate solution he had seen slight salivation follow. Since then he had used boiled water, and his cases had done much better than with either carbolic acid or corrosive sublimate."

Dr. E. A. Follansbee, of Los Angeles, agreed with Drs. McMonagle and Smith, saying that she had used the boiled water in her operations for about three years, and had found it reliable and much safer.

We have recently noticed reports of several laparotomies having been performed by different persons successfully without the use of any antiseptic solutions, using instead only hot water. And it is well known that Dr. Bantock, of London, uses only hot water in all his operations, discarding antiseptic solutions entirely, both for instruments and for perfectly cleansing wounds and cavities. Yet our London letter, in *THE JOURNAL* of April 20, 1889, says, concerning Dr. Bantock, "his results are unsurpassed." If the proper use of hot water is thus capable of yielding results that are not surpassed by any antiseptic solution, in the practice of abdominal and pelvic surgery, it certainly has the advantages of being cheap, ready at hand and entirely safe.

A NEEDED PRESCRIPTION.

The intensity with which Americans apply themselves to business is everywhere proverbial. Gigantic corporations, manufacturing and commercial industries, and business demands of every sort, lay upon men burdens too heavy to be borne. As a result, vast numbers succumb prematurely and seek medical advice as to the best means for relief. Absolute *rest* is the obvious necessity, and so the mountain air, the sea-side resort, or the ocean voyage, is the thing enjoined. The advice was timely and wise, and the results are usually highly satisfactory.

Now it often happens that the very same advice which the doctor gives to his patients should be

* See Occidental Medical Times, May, 1889.

followed by himself. From labors so imperative and so exacting, duty to himself, to his family, and to his patients, often requires that a physician shall religiously set aside a brief portion of each year that he may turn aside and rest awhile. The prescription which *THE JOURNAL* proffers to its patrons is more particularly applicable to the practitioners in the Mississippi Valley and the regions which lie beyond. It is as follows:

Leave home this year early in June, spend a week among the lovely New England mountains, and instead of an ocean voyage, and the undesirable sea-sickness incident thereto, seek a sea-side resort for one full week in one of the oldest and most lovely New England towns, and while in attendance upon the Annual Meeting of the American Medical Association the recuperated physician will not soon forget the pleasure and the benefits of another week's sojourn at NEW-PORT-BY-THE-SEA.

EDITORIAL NOTES.

NEW MEDICAL JOURNAL.—*The Kansas Medical Journal*, a monthly periodical of thirty-two pages, has made its appearance on our table. It makes a good appearance both in its typographical execution and in the character of its contents. It is published at Topeka, Kansas, and edited by a committee consisting of Dr. W. L. Schenck, Osage City, and Drs. G. E. Minney and S. G. Stewart of Topeka, Kansas.

DR. HARVEY LINDSLEY, of Washington, D. C., died April, 28, 1889, at the advanced age of 85 years. He was one of the founders of the Medical Society of the District of Columbia; a Professor in the National Medical College several years; and was elected President of the American Medical Association at its first annual meeting, in Washington, in 1858.

PROPOSED CHANGES IN THE CONSTITUTION OF THE ILLINOIS STATE MEDICAL SOCIETY.—We have just received a copy of *The Peoria Medical Journal* for April, containing an abstract of the changes proposed in the Constitution of this State Society, by a Committee appointed at the annual meeting of 1888. Several of the propositions presented by the Committee should receive the careful consideration of the members before deciding in favor of their adoption. The proposi-

tion to change the *time* of the annual meetings from the *third* to the *first* Tuesday in May, is particularly objectionable, as that is the same day that nearly all the meetings of the American Medical Association have been held when the *place* has been south of the line of New York and Chicago. There should be a full attendance from all parts of the State.

ASSOCIATION NEWS.

American Medical Association. Fortieth Annual Meeting.

Section on Laryngology and Otology.

In addition to the list published May 4th the Secretary has received promises of papers from the following gentlemen. Seven of these have given only conditional promises, but it will be seen that the Section has secured absolute promises of forty papers, and promises of eleven more, most of which we may reasonably expect will be forthcoming. The Secretary desires specially to urge those who have been in any doubt about their ability to write, to make a special effort for this first meeting of the Section. The large number of papers secured must not be taken as an excuse for not writing, but each and every one should remember that his pledge may be the main reason with several physicians for making a long and expensive trip to the meeting of the Association.

The officers of this Section again urge their personal friends to make an extra effort to help them at this time.

The following names complete the list of those from whom we expect papers: J. E. Schadle, J. L. Thompson, J. H. Bryan, W. Freudenthal, Chas. Stover Allen, Frank H. Potter, J. W. Gleitsman, Louis Jurist, J. B. Lippincott, H. A. Johnson, Robert Levy, Joseph A. White, C. W. Johnson, J. D. Arnold, F. S. Crossfield, W. K. Simpson, Wm. Porter, D. N. Rankin, J. H. Bryan, Jonathan Wright, Arthur Duncan, E. R. Lewis, Max Thorner, H. Clinton McSherry, F. I. Knight, J. Solis-Cohen, J. C. Mulhall, W. E. Casselberry, S. J. Radcliff.

E. FLETCHER INGALS, M.D., Secretary,
70 State St., Chicago.

W. H. DALY, M.D., President.

Section on State Medicine.

The following additional papers have been received:

"Bacteriological Examination of Several Native Mineral Waters in the Bottled State." Dr. George Minges, Dubuque, Iowa.

"Climatological Characteristics of Salt Lake City." Dr. F. S. Bascom, Utah.

SOCIETY PROCEEDINGS.

Obstetrical Society of Philadelphia.

Thursday, April 4, 1889.

THE VICE-PRESIDENT, W. H. H. GITHENS,
M.D., IN THE CHAIR.

DR. G. E. SHOEMAKER described an improvised waterproof drainage-pad for operations.

The only point of the arrangement here described is that it may be improvised in any household, even the poorest; and it is not intended that it shall take the place of the excellent device so widely advertised by an instrument-maker, except in emergencies. It happens to every one, however, to be called upon to do various minor operations when out of the reach of all formal apparatus, and in a number of cases where it was desirable to use water freely without wetting the bed or the patient, the writer has obtained the greatest comfort and satisfaction by the following means:

The necessary material, which can be had anywhere, consists of a sheet or thin coverlet and a piece of rubber cloth or table oil-cloth.

The sheet is folded twice, and then made into a tight roll about three or four feet long to form the rim. This roll, laid near the edge of the bed or table, is bent in the form of letter O, with a six-inch opening on one side of the O, the ends of the roll at this opening being fastened by safety-pins strongly to the edge of the mattress or the cover on the table.

When the rubber cloth is thrown loosely over this, a basin is formed which is open at the edge of the bed, and fluids readily find their way into a vessel on the floor to which the rubber cloth leads. Even a prolonged perineum operation, under constant irrigation, may be accomplished without any disarrangement or leakage. The same arrangement will be found to be of great assistance to patients in that troublesome procedure, the daily hot-water douche.

This may, of course, be called only an adaptation of the idea in the advertised pad before referred to. It may also be called a modification of the waterproof sheet which every woman has used on her bed since the deluge. The only object here is to call attention to the fact that we can, any of us, by simply making a curved ridge in this sheet, and paying some regard to the ordinary laws of hydrostatics, make for ourselves in five minutes a very great convenience, and save our patients and their attendants a good deal of trouble and annoyance.

DR. W. S. STEWART narrated the removal of a large, adherent, degenerated, parovarian cyst:

A young lady, æt. 24 years, was brought to our hospital from New Jersey, by her physician,

for examination and such treatment as should be determined on. I found in the left iliac region a hard mass, which, at first examination, seemed to be solid; but a more careful examination with the finger in Douglas' cul-de-sac, with palpation from above, revealed some fluctuation. On moving the uterus, the mass was found to be adherent to that organ, causing some doubt as to whether or not it was a true ovarian trouble. In consultation with my *confidère*, Dr. Montgomery, it was decided to remove the tumor, as from the history it evidently caused much suffering, with rather increased pain, distress, and irregular menstruation, and was developing more or less rapidly.

Two days later the patient was put on the table, and she almost died from the ether before the operation began. I was kindly assisted by the resident Dr. Hughes, chief of clinic, Dr. West and Dr. Dorman. On reaching the upper portion of the tumor, I found it adherent to the omentum, to the small bowel, to the walls of the abdomen, to the uterus, and to every part with which it was approximated. It was also deeply seated in the pelvis. On introducing the trocar, I found that the tumor was filled with pus. The liquid degenerated, and we had a pent-up septic fluid in an almost aseptic condition. I rapidly removed the disintegrated sac from the parts to which it was attached, working as rapidly as possible, for the patient seemed to be going to die every moment. Not finding any pedicle, I was obliged to dissect the sac off as carefully as possible, and was delayed some time in getting it off. Considerable oozing, but no special bleeding, occurred. I found the adhesions to the uterus so firm that it was impossible to separate the sac, and if I had used a knife, considerable time would probably have been required in ligating the vessels. I therefore transfixed the side of the uterus with a ligature, and tied both above and below, and clipped off the margin as close as possible without affecting the ligature. Where the sac penetrated deeply into the tissues of the pelvis, I ligated as closely as possible and clipped off the remaining portion of the sac. The pus escaped considerably through the pelvis, and I thoroughly irrigated with pure warm water and stitched up the wound, leaving a drainage-tube in position. The patient was returned to her room with a temperature of 96°, almost moribund. Under the use of restoratives, hot bottles, hot applications, and a hot room, she soon regained her normal temperature, and made a speedy recovery without an untoward symptom. The stitches were removed on the eighth day, and the drainage-tube allowed to remain until the ninth day. The present prospects are, that the patient will entirely recover, and is now (third week) going about her room in the hospital.

As bearing on the cause of this trouble, I would say that I have learned that she lived on a

farm, and that four years ago she took the part of a man in the harvest-field. Her work was pitching the sheaves from a platform in the barn up into a higher portion of the mow. Not having the strength to use the long-handled fork, she put her elbow down on the affected side, and with this as a fulcrum, and the other hand as a pry, she threw the sheaves up. In this way, possibly, she injured herself. This is a suggestion worth knowing, as a possible cause for this development. At this time she was wearing corsets, and this would confine everything, so that the pressure of the elbow caused an additional strain or possible contusion.

DR. M. PRICE: One point that I have noticed in regard to these pus tumors is, that the danger of the operation does not seem to be increased by the fact that they are filled with pus. The patient referred to had probably been in a septic condition at the time of operation, and the moment that the tumor was removed and thorough drainage instituted, her chances probably were as good, if not better, than in a case of simple tumor not in a sloughing condition. I have never seen a tumor filled with pus give any trouble after removal. So far as I know the patients have always done well.

DR. J. M. BALDY: I must disagree with Dr. Price. It seems to me that the presence of pus and of a septic condition would considerably increase the risks of operation. In the removal of a cyst in which there had been no septic trouble, and before suppuration had taken place, the woman would be in good condition, and probably have suffered from no symptoms, save, perhaps, those of slight enlargement. In a case of that kind the risks would be small. Where a woman becomes septic from whatever cause, the risks are seriously increased.

In regard to the cause suggested, I think that there is no very good basis for assuming that this had any effect. I do not think that the pitching of sheaves and the pressure of the elbow would cause the development of such a tumor. This might have been an incidental exciting cause, but that it was the primary exciting cause we have not sufficient ground for believing. Many women develop tumors without having any severe labor of that kind. On the other hand, I have seen women who have performed such labor daily, to the severity of which I can personally testify, and never develop anything like ovarian trouble. The wholesome exercise of working in the field would, in a healthy woman, predispose rather to good health than to disease.

DR. M. PRICE: It is a well-established fact in surgery that a recent injury in a previous healthy individual requiring a surgical operation is more dangerous than where the operation is for an old injury. The chances of the second patient would be a hundred-fold better. I had my limb broken.

A healthier boy never lived, and for six weeks it was a struggle for life. A year later I had the limb amputated, and I can testify that I have suffered more from the extraction of a tooth than from that operation. If the limb had been operated on at the time of the injury, I should probably have died. I was not used to suffering. There had been no preparation. I do not pretend to say that the presence of pus gave the patient a better chance, but the suffering prepared her for a surgical procedure which, in her case, would be more successful than it would be in a case of simple tumor with adhesions. In uncomplicated ovarian tumor, the operation is one of the simplest in surgery. The case reported was probably one of intra-ligamentous cyst, or perhaps a twisted pedicle. If the operation had been performed before pus appeared, with these strong, unchanged adhesions, her chances would not have been so great as after sloughing had taken place, and degeneration of the adhesions had begun. There was less hæmorrhage and less shock. The patient had been prepared for what had to be done.

DR. W. L. TAYLOR: I would agree with Dr. Baldy that the removal of a sloughing cyst would cause greater risk to the patient than the removal of a simple ovarian tumor. A patient with a sloughing cyst is necessarily suffering from septic trouble. She is weak and depressed, and her vital powers are lessened. In an ovarian cyst the vital forces are in a good condition for operation. This is the only point to which I would refer, as I did not hear the paper.

DR. STEWART: I think that both Dr. Baldy and Dr. Price may be right. Where the septic condition has not reduced the patients to such an extent as to preclude their recovery, they often resist shock and recover rapidly. The shock is less severe than in an operation in a patient in vigorous health. I can understand this, and have seen it in some cases. In my case the patient scarcely survived the operation; but when the effects of the shock had passed off, her recovery did not seem to be influenced whatever.

DR. J. HOFFMAN read the following:

CRANIOTOMY FOR A CASE OF HYDROCEPHALUS, with a discussion of the Technique of the Operation, together with a Consideration of the Conditions that demand it.

At midnight of Dec. 23, 1888, I was called by a midwife to see a woman. She was unable to deliver, after, as I afterwards found out, continual effort for four hours. I found the woman much worn out by her pains, which were ineffectual, though her pulse and condition were, all in all, good. Examination showed a large head, well engaged, lying transverse in the pelvis, the occiput to the left.

I at once put on the Pouliet forceps but though

they were accurately applied, was unable to rotate the head, the forceps finally slipping. After a great deal of difficulty, I again succeeded in applying them, with like result, slipping on traction. A third effort to apply them was only successful after placing the woman on her side. Traction, was, however, no more successful than before. I then desisted from further efforts at delivery, two hours having elapsed, and brought Dr. Joseph Price in consultation. Dr. Price, after a great deal of trouble, succeeded in applying the Tarnier traction forceps, with no better success, however, than had followed the use of the Poulet instrument. From the constant slipping of his forceps, Dr. Price suspected a hydrocephalic head, and so expressed himself. I, on the contrary, thought otherwise, as the bones while not so firm and resisting as usual, did not seem to be sufficiently flacid to indicate dydrocephalus, at least to me. Events, however, proved the correctness of Dr. Price's suspicion, or rather diagnosis; for there being no heart sounds when the head was perforated, the rush of water left no doubt as to the true condition. The instruments used were those presented to-night, as they already have been before. They consist of a crushing forceps, which, from its pelvic curve, is as readily introduced and applied as the ordinary forceps. The non-fenestrated blades afford the safety of a speculum for perforation, and leave no manipulation necessary after that part of the operation has been performed. All considering this subject seem to take for granted that the crushing instrument in all craniotomy procedures must be applied after perforation. This, it seems to me, supplies one of the greatest dangers of the operation, and conduces to an unnecessary fatality. The preapplication of the crushing instrument not only protects the maternal soft parts from the danger of injury by the perforator, but also a more exact adjustment, by a gradually applied force as the head is reduced and its contents evacuated by the perforator. The ease of application of this instrument can be appreciated by any one familiar with the ordinary forceps.

The point of this perforator Dr. Price has intended to be protected by the buckskin finger, and the skull pierced through it. This is, however, not really necessary, as the speculum afforded by the crushing blades, together with that afforded by the introducing finger, makes the leather unnecessary.

The combination of instruments afforded in this craniotomy set seems to leave nothing further to be desired, even if further destruction of the fœtus is necessary, than the mere reduction of the head. For the consideration of the conditions which demand this operation, there is at present, perhaps, a greater necessity than the mere statement of its technique with any set of instruments whatever. Many of our recent

writers apparently desire to condemn it in all cases whatsoever upon the living fœtus without exception. As a type of these may be taken the views of Dr. Busey, in the *American Journal of Obstetrics*, January, 1889. These writers, of which Dr. Busey may be taken as a type, fail to appreciate the fact that we need go back no further than Hodge to find that in cases where the short diameter of the pelvis is two inches or under, the Cæsarean operation is to be preferred, as affording a better prospect for the mother, while having the strong recommendation of affording a good prospect of safety to the child; this, too, before the improved Cæsarean operation was devised. These writers seem, too, to fail to appreciate that long ago as the writer referred to, to go no further back, the early performance of the Cæsarean section was specifically stated as justifying strong hopes for "the salvation of both mother and child." It is not the purpose of this paper to discuss the relative merits of the Cæsarian section and craniotomy, nor the comparative values of the mother's and the infant's life. It is not possible to avoid, nevertheless, the observation that those writers who unhesitatingly apply the statistical method at arriving at conclusions relative to these in favor of the first operation, seemingly forget that the dangers of craniotomy almost entirely lie within the limits already admitted into the domain of legitimate Cæsarian section, and that outside of these cases the danger to the mother is almost absolutely nothing, as admitted by Lusk in his late discussion. They seem, too, to consider that craniotomy, to be successful, must be done by the expert, and that the Cæsarian section is the safer, no matter by whom performed. To this we submit a positive disagreement, though even Dr. Tait has gone so far as to say in effect that the removal of the pregnant uterus is a simple operation. Dr. Busey refers to the "dream of Tyler Smith, as to the abolition of craniotomy from the obstetric practice."

When we consider the paper of Tyler Smith, to which reference is made, we can readily understand how opportune was the plea. The table of cases therein quoted from cases in "British Practice," affording excuse for craniotomy, state twenty-five indications for its performance, among which are, to wit: arm or shoulder presentations, rupture of the uterus, face presentations, bands or cicatrices in the vagina, placenta prævia, rigidity of the perinæum, occipito-posterior presentations, etc. "With such 'indications' as these there was need of a voice crying in the wilderness."

The point to be here considered is whether the decial of the abuse of any operation necessarily implies that there is never any requirement or justification of such operation. We think not. No one will dispute that where there is danger

to the mother in the performance of craniotomy, the conservative operation of Cæsarian section should be performed. On the other hand, where there is no danger to the mother whatever, I consider it questionable whether any obstetrician here present would subject his own wife to the danger of a capital operation in order to save the life of the child. Secondly, in cases where such deformity as hydrocephalus or spina-bifida is discovered, I do not believe that the life of the child should be considered as compared with the mother's in the danger of the Cæsarian section, providing that the pelvic contraction be not so great as to bring craniotomy farther beyond the danger line than the Cæsarian operation.

The application of the same principle in the case of monsters needs no discussion.

The woman recovered without a bad symptom.

DR. STEWART: I would say a word in regard to this case of hydrocephalus. I have had two or three such cases and have had no difficulty in delivering after penetrating the skull and allowing the water to escape. I consider this an ingenious instrument, but I have used the old-fashioned perforator, cutting both ways. After introducing the blades and separating them you have a free escape of the liquid. The skull then collapses and there is no further difficulty. You can deliver then with any forceps. Such has been my experience.

DR. DANIEL LONGAKER: I have not used this instrument of Dr. Price, but I can readily see that in a certain class of cases, *e. g.*, hydrocephalus, it would be excellent. I desire, however, to say, that in craniotomy, and especially in cases of marked deformity of the pelvis I have used with the most marked satisfaction the cranioclast of Braun, and the perforator of Blot. I do not see how in ordinarily careful and skillful hands any injury can be done with this perforator. The trepan is certainly a safe instrument.

DR. J. PRICE: I have discussed this matter on several occasions, but the remarks of Dr. Longaker invite me to say something. The application of the instruments mentioned is difficult. When closed they occupy one inch of pelvic space. Much damage is often done, and the mortality in craniotomy has been largely due to injury of the maternal soft parts by this instrument. In one case the sacrum was trephined with the instrument alluded to. Hodge long ago called attention to the use of the ordinary forceps as a compressor. This instrument is made on the same principle, and the strength is in the handles. You can crush anything with this instrument. Anyone who can apply forceps can apply this instrument in any pelvis where the forceps can be applied. It can be applied in a pelvis with a diameter of one and a half inches. I have seen it successfully applied by beginners in the case of dead children without doing any mischief. The

instrument is used first as a speculum, second for fixation, and third for compression.

DR. LONGAKER: It is only necessary to refer to my own experience with cranioclast, and to confirm my favorable opinion of the operation. I will refer to a paper which can be found in the *American Journal of Obstetrics*, I think, for December, 1884. Cases by the fifties and hundreds are reported without a fatal result. This is a proof of the safety of cranioclast, which I consider the better operation where there is a high degree of pelvic deformity.

DR. J. PRICE presented specimens with remarks:

I desire first to present two fresh specimens. One was very unique, removed day before yesterday,—a case of double pus-tubes and double ovarian abscess, with pus in the cellular tissue. The ovaries were cheesy shells, and they both ruptured in the removal. The pavilions were entirely gone. There was no hesitation on the part of those present in regard to the character of the fluid. It was pus. Much has been said in regard to the character of the fluid from this locality. If such liquid was removed from other parts of the body there would be no question in regard to its character. I open one of these tubes before you, and I trust that you will examine the fluid carefully.

This is a typical case of ovarian cyst, no larger than an egg, with no semblance of the pavilion. This contained fluid; but I do not claim that it was pus. The cyst was strongly adherent, and I had to shell it out.

Here is an enormous ovarian abscess, unquestionably due to gonorrhœa.

You will find that the most of these tubes have been cut through, and a stick inserted. Most of them on removal were as large as the uterus. All of the patients were great sufferers. I am sometimes asked what becomes of the patients who refuse operation. In five of these cases I had urged section from a few months to several years previously.

This specimen is from a woman to whom I urged operation five years ago. It is an enormous dermoid cyst, encapsuled by omentum. It looked like a hopeless case, but she made a good recovery.

Here are two small ovarian cysts, in which it would have been easy to guess at the diagnosis of extra-uterine pregnancy. Here are typical pus-tubes, and you can bear in mind that the character of the fluid in these cases was that of the tubes before you.

I have here a group of four or five small cysts, the removal of which I consider important. These patients suffered severe pain. These occurred in young women who were able to definitely locate the seat of the pain. One of these small cysts developed in a recently married woman

19 or 20 years of age. She saw me three days ago, three months after the operation, and states that she has missed the last two periods.

This small tumor was removed by Dr. Müller, of Germantown. The ovary is healthy, and you see a very pretty parovarian cyst. The woman made a speedy recovery.

I have here two extra-uterine pregnancies. The placenta and clot in one is seen in the tube, and can be removed. This is unquestionably an extra-uterine pregnancy. In the other the placenta is inside. The specimen has been examined by Dr. Piersol and Dr. Meigs, and they state that it is undoubtedly extra-uterine pregnancy. This is a hydrosalpinx of the opposite side of the first case. Here you have a beautiful illustration of the existence of double disease. On one side desquamative salpingitis, hydrosalpinx, and pus-tubes, and on the other side extra-uterine pregnancy. The second case was an example of double tubal pregnancy, and both tubes had ruptured. This woman lived after the uterus had been curetted twice, and iodine had been injected after the second operation. The bleeding continued, and until the abdomen became distended, it was not deemed necessary to do anything further.

I desire to say that four of these operations followed Emmet's operation for laceration of the cervix. If there exists any tubal disease, this is a dangerous procedure. Some one has remarked that Emmet has gone back on his operation. He has uttered a word of caution because of the mortality in the hands of some of his followers. Many of the cases come back to him. Where there has been tubal disease, many deaths have occurred, and many patients are invalids. I do not condemn the operation. I know it to be valuable in well-selected cases, when you can exclude the existence of tubal diseases.

DR. M. PRICE: Here again comes up the question of the preparation of the patient by the leakage that has been going on in the pus cases. I have seen at least fifty pus cases in the last two years. Very rarely is it that you can deliver the tube without some leakage and perhaps rupture. These cases have recovered and do better than some simple cases. Our nurses always prefer a pus case where a drainage-tube has been used. Where a patient is poisoned and dying, no one makes any claim that there is any advantage; but where inflammatory changes have been going on for a long time, there is, unquestionably, a preparation. I have never seen but one case of pus in the pelvis die. That case died from starvation from the nurse drinking the milk. These cases recover if the enucleation has been done with care, and irrigation and drainage properly performed.

DR. HOFFMAN: In regard to the gonorrhœal origin of these troubles, I would say that two

weeks ago I had a child two weeks old brought to me with sore eyes. I applied nitrate of silver, and gave explicit directions as to treatment. In three days the child lost its sight. I found that the mother had gonorrhœa of the most virulent form. I also found ovarian and tubal trouble very marked on one side. She had been married only a short time and previously had known no trouble. There seems to be a connection between the inflammation of the child's eyes, the gonorrhœal discharge from the vagina of the mother, and the trouble in the pelvis.

DR. J. M. BALDY: I do not care to say anything in regard to pus-tubes, because my views have been often expressed. I would again take exception to the view of the preparation of the patient by sepsis. It is true that in many surgical injuries better results are secured where the operation is done some time subsequently than when it is done at once. This is not because of septic infection. Shock is here a great element. This brings up the old theory that it was better to allow ovarian tumors to reach a large size, in order that the peritoneum might be prepared, etc. We have long since given this up, and we shall quickly have to give up the idea that the patient is prepared for operation by being septicallly infected.

Dr. Hoffman has referred to the connection between inflammation of the child's eyes and gonorrhœa in the woman. Individual cases do not go for much. The fact that the child has inflamed eyes does not indicate positively the existence of gonorrhœa. The nurse's hands being contaminated by the septic lochial discharges may infect the child's eyes.

In discussing this matter in the Pathological Society the other night, the president stated that he had seen unquestionable gonorrhœal pus-tubes removed from a single woman. On inquiry, however, he admitted that the woman had had two criminal abortions a short time before. This was probably the cause of the inflammatory trouble, and this is the history of many of these cases. I protest against the view that assigns gonorrhœa as the cause of all of these cases. It is a dangerous teaching for ourselves as a profession, and it is dangerous teaching to the laity. If we teach the laity that all these cases, or most of them, are of gonorrhœal origin, we shall cause an unlimited degree of marital unhappiness throughout the country, and shall cause irreparable family troubles. We certainly have to have better and more scientific ground than mere clinical histories before we can accept this extreme view. Dr. Hoffman, in a recent discussion, cited the statistics of Bernutz and Goupil as a proof of this view. Out of ninety-nine cases, about forty-six were of gonorrhœal origin, and these were in the lowest class of women. Even by these picked statistics, and amongst this low class, over half

were of septic origin, and many of the supposed gonorrhœal ones I would be inclined to dispute. I must adhere to my opinion, that by all odds septic infection is the most common cause.

DR. M. PRICE: The report referred to was from Charity Lying-in-Hospital, with a record of fifty per cent. gonorrhœa. The remainder are attributed to sepsis and wounds during labor.

DR. W. H. PARISH: I would endorse what has been said as to the inadvisability of operating for lacerated cervix where there is disease of the tubes and ovaries. We know that salpingitis is often an extension from the endometrium, often gonorrhœal, sometimes septic. Thorough drainage is important, not only in the treatment of the endometritis, but also in the palliative treatment of the endo-salpingitis. By narrowing the uterine canal, we prevent the free escape of pus and other fluids, and aggravate the trouble. I consider it unwise and not safe to operate on these cases. Within the past week I was called to operate on a lacerated cervix. I had not seen the patient for twelve months. After etherization, I found evidence of tubal disease on one side and declined to operate on the cervix.

DR. J. PRICE: In regard to this question of percentage I agree largely with Dr. Baldy. He admits this evening what he did not admit in the discussion at the County Medical Society—that these cases are largely due to gonorrhœa. Criminal abortions, cold, and exposure are other common causes of such mischief. Mr. Tait, and many others, are operating on a simpler class of cases than we are. Operating to save lives has been the course of many Philadelphia operators. In all of the cases reported the operation was done to save life.

The operation should be rapid, every detail should be shortened. The ligature should be the finest possible. Large plaited ligatures are not absorbed, and are at the bottom of many sinuses. The ligature should be applied at the root of the tube. Complete delivery of the tube and ovary, tying at a good surgical neck; then thorough irrigation, with careful closure and perfect drainage. There are two things in which my convictions are as firmly fixed as in anything in medicine; and that is, first, the value of irrigation, and, second, the value of drainage.

Gynecological Society of Chicago.

Regular Meeting, Friday, Dec. 21, 1888.

THE PRESIDENT, CHARLES T. PARKES, M.D.,
IN THE CHAIR.

DR. W. W. JAGGARD read the following note, entitled,

TWO OBSERVATIONS OF TYPHOID FEVER DURING PREGNANCY.

I report the two examples of typhoid fever

during pregnancy, both on account of the intrinsic interest of the case, as well as to bring out the experience of others with this complication. Typhoid fever is of very frequent occurrence in Chicago, and the Fellows that have resided in the city for a considerable period can doubtless supply important facts that bear upon the reciprocal relations of this disease and pregnancy.

This note may be regarded as in a measure supplemental to the excellent discussion of typhoid fever, recently held before the Chicago Medical Society, at the suggestion of its President, and our distinguished Fellow, Dr. J. H. Etheridge.

Observation No. 1.—This case was observed and described by my friend, Dr. William M. Findley, of Altoona, Pa.

Mrs. M. H. Y., aged 24 years, Irish extraction, whose husband had been ill some six weeks with typhoid fever, was, after the initial prodromata, taken down with well-marked typhoid fever, May 7, 1873. Temperature and pulse ranging high in evening, with epistaxis and diarrhœa early. The case would not have attracted unusual attention except for the fact that she was pregnant, and her labor was anticipated on the 10th of May, 1873. She, however, was not taken in labor until the 15th of May. On the evening of the 14th of May I was called about 9 P.M., after my regular visits for the day, and found her condition as follows: Temperature 103°, pulse 140, respirations 36, with marked bronchial irritation and secretion—having had six characteristic stools during the day in spite of remedies—and the contractions of the uterus quite strong and regular, os dilated to half-dollar piece size and dilating. The heart being very feeble, and jactitation marked, with exhaustion coming on rapidly, I gave her, *ad libitum*, best port wine and brandy, so that in the four or five hours of labor she took about a quart of brandy, and about as much more port wine, with no other effect than to keep her in the same condition as I had left her before labor came on. In due time the labor was terminated, contraction was perfect, once the product of conception was expelled completely, and no untoward results followed. Although during labor her bowels were moved copiously some six or eight times, after labor the bowel trouble seemed to subside greatly, and she passed on to convalescence in some three weeks without marked irregularities, as in an ordinary case of uncomplicated typhoid fever. The secretion of milk was entirely suppressed, the mammary glands never showing any signs of activity during her illness.

The condition of the child, however, was remarkable. The entire cuticle or epidermis was shrivelled and creased as though it had been macerated in hot water, and in a day or two it was covered with bullous spots from head to foot, vesicular first, then pustular. As the boy was

healthy in other respects, in the course of a week or ten days the eruption, under emollients, was well, and the cuticle becoming detached was replaced by healthy skin tissue and the baby was well, except that as a young man he carries the cicatrices of some of the bullæ.

Observation No. 2.—This case came under my own observation. From the history of the case, written by Dr. B. L. Riese, I make the following extracts :

Mrs. A. McG., 23 years old, married June 17, 1888. Last menstruation June 10, 1888. Morning sickness six weeks after marriage. Husband and wife taken sick with typhoid fever about the 28th of August ; both admitted to Mercy Hospital September 4th. Husband died a few days later of a malignant type of the disease. In the case of the wife the disease pursued a typical course lasting about three weeks ; maximum temperature, 103.4 F. ; maximum pulse, 130. October 1st, several days after the subsidence of the fever, severe pains referred to the hypogastric region, hæmorrhage from the vagina. After irrigation of the vagina, indagation revealed the vaginal portion softened and the ovum presenting through the cervical canal. Plan of treatment, expectant, in the absence of serious hæmorrhage or symptoms of sepsis. October 3d, escape of liquor amnii ; on examination, fœtus protruding through the os externum ; removal of the fœtus, placenta and membranes by bimanual manipulation under aseptical conditions.

The patient made an uninterrupted recovery. The ovum corresponded to the fourteenth week. (Presented for inspection.) The apparent cause of abortion in this case was hæmorrhage into the decidua serotina and placenta fetalis. The extravasation occurred before the removal of the product of conception. This fact is evident from the characters of the clot, as large as an English walnut, and firmly imbedded within the placental tissue. The presence of hæmorrhagic endometritis may be inferred from the character of the decidua vera and chorion læve.

With reference to the mutually unfavorable relations of typhoid fever and pregnancy, experience teaches that pregnancy confers upon the individual no immunity from typhoid fever. Upon the other hand, the course of this disease is commonly modified unfavorably, and the fever in turn exercises a distinctly prejudicial influence upon the course of gestation. The tendency to the interruption of pregnancy is more marked than in any of the acute infectious diseases, with the possible exceptions of small-pox and cholera. In about two-thirds of the cases collected by Kaminski, Zülzer, Scanzoni, and others, pregnancy was prematurely interrupted.

The chief causes of abortion or premature labor are to be found :

1. In the elevation of maternal temperature

causing death of the fœtus by isolation, or its premature expulsion by thermic irritation of the uterine musculature.

2. In the almost constant hæmorrhagic endometritis, illustrated by the specimen presented.

3. In the depression of the maternal blood-pressure with asphyxiation of the child.

4. Until within a recent period the transmission of the infection through the placenta from the mother to the child has been regarded as possible, but not demonstrable. Lately, however, Widal and Chantemesse have detected the bacillus, alleged to be characteristic of typhoid fever, in the blood of a fœtus corresponding to the fourth month.

The unfavorable influence of pregnancy upon typhoid fever lies especially in the tendency to abortion or premature labor at a time when the loss of blood and the muscular exertion necessary to effect the expulsion of the product of conception may precipitate the lethal issue from exhaustion. There is also increased risk of perforation.

DR. E. J. DOERING: I would like to have Dr. Jaggard tell us whether or no there are any statistics by American authors. I have had two cases, one last September, in which the fever lasted from three to four weeks, and in both of which pregnancy was not interrupted. One lady was in the sixth month of pregnancy, the other in the seventh month. The temperature in either did not exceed 104.5° F. It is my experience that these cases are liable to go through without interruption. Before the discussion is closed, it seems to me it would be well to have the experience of members present. They must have seen such cases, and I do not think we should let the subject go by without all the members stating their experience. In my last case I expected daily that the patient would miscarry, but to my surprise she went right along. That was quite a severe case. In the other case the fever did not go quite so high, but the last case was typical, and lasted fully four weeks. I not only thought she would miscarry, but had grave doubts as to her recovery. But to my surprise and pleasure she passed through safely, and returned to her home in Mobile some months later.

THE PRESIDENT: If my recollection serves me, I am satisfied I have seen several cases of pregnancy complicated with typhoid fever, and I am quite sure that every one of them miscarried where the pregnancy was early; in those in which the typhoid fever came on towards the later stages of pregnancy the patient not only miscarried, but lost her life as well. Of course I cannot now recall the exact number, nor the cases, but that is the recollection I have. It seems to me I have often heard doctors say that it is rather an impression among medical men, that if they have a case of typhoid fever in pregnancy it is likely to be followed by a miscarriage.

DR. JOHN BARTLETT: I recollect but one case. That was many years ago, in which a woman pregnant about four months, and in the third week of typhoid fever, doing quite well, was taken in abortion. She went through the process of labor satisfactorily, but died the next day.

DR. BAYARD HOLMES: The transmission of the bacillus of typhoid fever through the placenta is a matter worthy of consideration. We know that in certain cases of anthrax the foetus is not infected, although the mother's blood is full of the bacilli. After the birth of the living, healthy foetus at term, a sufficient period follows for the incubation of the disease, and then appears anthrax: first in the umbilicus, then general symptoms of anthrax septicæmia. In other cases, however, the foetus is infected with the anthrax *in utero*. In a paper that I presented to this Society some months ago, I held that the pyogenic infection of the foetus through the placenta was a comparatively rare occurrence. Since that time I have paid considerable attention to that subject, and I conclude that my statement should be limited. All cases in which infection of the foetus *in utero* has or has not taken place can be reconciled. In cases of sapremia with the presence of multiple known bacteria in the blood of the mother, those bacteria are all included in phagocytes. These phagocytes are sufficiently powerful to prevent the multiplication of the microbes, although they are not able to destroy them. This accounts for those typical cases of Bollinger, in which the foetus was not infected, although the blood in different parts of the body of the mother sheep contained the anthrax bacillus. Whenever, on the other hand, the sapremia has advanced to the condition of septicæmia, and the phagocytes have been overcome, and multiplication of the bacteria takes place at their expense, then embolism occurs in the peripheral arteries, that is to say, in the uterine wall, and the multiplication of the microbe follows at that point in close proximity to the foetal circulation. In this way they force themselves onward into the capillaries of the placenta, and the foetus is infected. In relapsing fever, and all cases of septicæmia, the infection of the foetus is the rule. Typhoid is a form of septicæmia, at least in the latter part of the first week. The symptoms of septicæmia are then present, viz.: capillary embolism in the skin forming hæmorrhagic spots, the characteristic rose spots of typhoid; ptomaine poisoning, which either raises or lowers the temperature; internal capillary embolism resulting in splenitis, pneumonitis, hepatitis, nephritis, and in cases of a pregnant patient, hæmorrhage in the distended capillaries of the decidua in close proximity to the placenta. At first it is simply a miliary hæmorrhage, but as the destruction of the capillary wall increases by coagulation necrosis, a considerable quantity of blood escapes between the placenta

and the uterine wall, and contractions of the uterus are initiated which ultimately expel the contents of the womb.

The case which Dr. Jaggard reports from Pennsylvania seems to me to be one of acute pemphigus (Denme), and due to a secondary mixed infection of the mother, and not directly to the typhoid disease. Pemphigus is a relatively frequent form of secondary infection in children, but in the adult its manifestations are so trivial that a diagnosis is difficult. On this account the mother who was primarily infected seemed to escape, while the non-resisting child suffered the terrible disfigurement of the disease.

DR. JAGGARD, in closing the discussion, said he was unable to find in the literature of the subject any statistics from American sources that related to the items touched on in his communication.

The rôle that elevation of maternal temperature plays in the causation of death of the foetus depends chiefly upon the rapidity with which the rise occurs, and the duration of the pyrexia. As pointed out by Doléris, Doré, Max Runge and others, if the elevation of maternal temperature occurs slowly, and if it be of brief duration, the foetus commonly escapes injury.

LETTER FROM LONDON.

(FROM OUR REGULAR CORRESPONDENT.)

A new Penny a Week Collection Scheme in Connection with the Hospital Saturday Fund—Recent Small-pox Epidemic at Sheffield—Case of Fractured Spine—The Hot Water Cure—Prize of £100, and a Gold Medal for the Best Essay on the Etiology and Prevention of Yellow Fever—Street Ambulance Organization for London, etc.

A new penny a week collection scheme in connection with the Hospital Saturday Fund is about being inaugurated. The scheme is to raise 500,000 pence weekly (£100,000 annually) and thus remove the debt from the London hospitals. In the various hospitals in London at the present time there are 2,637 unoccupied beds and quite 2,000 would be occupied if the funds were forthcoming. The promoters of this new movement invite the assistance alike of employers and employed in collecting subscriptions, which will be purely voluntary and limited to one penny a week.

The recent severe epidemic of small-pox at Sheffield forms the subject of an exhaustive report to the Local Government Board by Dr. Barry, who has accumulated an enormous mass of facts dealing with every aspect of the outbreak, its origin, its spread through the town, and the

influence of vaccination in preventing its further spread. The full magnitude of the outbreak is attributed by Dr. Barry to the spread of infection from the small-pox hospital to which the earlier cases were sent. Twenty-three maps of the most populous portions of the town are annexed to the report. Around the fever hospitals a number of rings are drawn at intervals of 1,000 feet. In the first two maps the cases are scattered indiscriminately about the town, but at an early period they showed signs of congregating around the hospital. This tendency soon became very marked. The hospital was the centre, as it were of the epidemic. As the months wore on the infection spread steadily over a wider area, the cases moving outwards from the hospital like waves on the surface of a pond from the centre of disturbance. There is no possibility of doubt, after an inspection of these maps, that in some way or another this hospital, situated close to the work-house, and on the edge of a very populous district served as a focus of infection. A few sporadic cases were taken there, and served as the centre from which the actual epidemic spread. During fourteen weeks, from May 21, to August 27, while the hospital was in full operation, the proportion of infected houses within a radius of 4,000 feet was seven times that in other parts of the town. Within 1,000 feet of the hospital the proportion was three times as great as in the next zone between one and two thousand feet away. This again was three times as severely scourged as the next zone, between two and three thousand feet, while that had twice as large a share of infected houses as the outermost zone at a distance of from three to four thousand feet. Even this outside zone had a proportion of infection double that of the rest of the town. At subsequent periods the distribution altered in consequence of the outward spread of the infection. During February and March, 1888, the operations at the hospital were lessened owing to the removal of all acute cases to another hospital. The result was at once a rapid falling off in the number of cases within the hospital area. Dr. Barry's report appears to show that a small-pox hospital is quite out of place in the centre of a populous district, and is a very great source of danger to the population which it is intended to protect.

The statistics of the attacks on vaccinated and on unvaccinated persons are of the utmost interest and importance. Thus while among every thousand unvaccinated children below 10 years of age there were 101 cases with a death-rate of 44, there were only five cases in every thousand of vaccinated children and a death-rate of .09. The contrast was equally marked among the children actually living in houses invaded by the disease. Thus while the rate for vaccinated was 78 with a death-rate of one, that of the unvaccinated was 869 with a death rate of 381. Among older per-

sons the contrast was not so great, but it was still decisive. The result may be shortly summed up by saying that a vaccinated child is 381 times less likely to die of small-pox than one who is unvaccinated, while among older people those once vaccinated were 51 times, and those twice vaccinated 640 times, less likely to a fatal attack of the disease than those who had never undergone the operation of vaccination.

Mr. Herbert Allingham lately had an interesting case of fractured spine under his care. The patient, æt. 31, was admitted into hospital having fallen 40 feet, causing a fracture. He was paralyzed from below the level of the ensiform cartilage. As he did not improve, in fact, seemed to lose ground, Mr. Allingham trephined the spine through an incision 10 inches long. It was seen that the lamina of the sixth vertebra was badly fractured and depressed. He therefore, with the bone forceps, snipped off the laminae and spinous processes of the fifth, sixth and seventh vertebrae, exposing the cord for about 4 inches. The operation took an hour and a half and the wound was dressed antiseptically. Healing had taken place in about ten days, and the symptoms of ascending changes checked. Some amount of improvement subsequently took place, the level of the paralysis being brought down to the umbilicus. Mr. Allingham considers that by timely trephining inflammatory ascending changes are prevented, that no bad symptoms follow the laying open of the spinal dura mater, and that the operation, although tedious, was not difficult, and does not lessen the chance of recovery.

There is quite an enthusiasm at present in London for the hot water cure. The victim of indigestion, eczema, headaches, palpitation, sleeplessness and other ills, imbibes a half-pint of very warm water night and morning, with finely minced beef for his food, and feels, it is said, restored to youthful vigor by the simple regimen. Many busy city men are stated to have received much benefit from the treatment.

A medical man near London has just met with a tragic death. His child was attacked with diphtheria and he found it necessary to perform tracheotomy, and it was in sucking the tube, which had become blocked, that Mr. C. I. Moore contracted the disease, which terminated fatally not only in his own case but in that of his child also.

The Parkes triennial prize of £100 and a gold medal for the best essay on the Etiology and Prevention of Yellow Fever, has just been awarded to Surgeon Firth of the Army Medical Staff. The subject for the next prize is "The Influence of Soil as a Factor in the Production of Disease, especially in Hot Climates." The competition is open to all medical officers of the army, navy and Indian services of executive rank on full pay.

A sufficient sum of money, £1,500 in all, has

been realized to cover the initial expenses and the cost of working for the first year of the excellent scheme of a street ambulance organization for London. The idea has been worked out by the Hospital Association, who have obtained a strong committee. It has been decided to invite the chief of the police and fire brigade to join the committee. Within two months it is hoped the system will be in working order.

Professor Virchow is stated to be busily engaged in rewriting his great work on Cellular Pathology. He expects to conclude his labors at a comparatively early date.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

The Relation of the Tubercle Bacillus to the Etiology of Phthisis—The Early Diagnosis and Prognosis of Phthisis—The Specific Nature of Phthisis—The Influence of the Microbe Theory on the Treatment of Phthisis.

At the first meeting in May, of the Academy of Medicine, Dr. W. B. James read a paper on *The Relation of the Tubercle Bacillus to the Etiology of Phthisis*. The result of the enormous number of original investigations which had been carried on since the discovery of the bacillus, in 1882, he said, had been to confirm the correctness of Koch's conclusions. It was also fairly well established now that the tuberculous process is capable of setting up inflammatory action in adjacent tissues which may be either acute or chronic in character. By pulmonary phthisis he understood a tuberculous inflammation of the lungs, and he therefore considered any secondary and contributing cause or causes as unnecessary. Clinical experience taught that different individuals respond very differently to the tuberculous infection, and also that the same individual responds differently to it at different times. In this connection he referred to the results obtained by Dr. Trudeau from exposing animals inoculated with tuberculous virus to different kinds of environment. In the dead-house of the New York Hospital, he said, he had been struck with the large number of individuals whose lungs presented lesions which showed that they had at one time been the subjects of phthisis and had recovered from it. Whether or not any previous lesion of the lungs was necessary for the development of tuberculosis he did not think was established. The sum of clinical experience seemed to indicate that tuberculosis develops more readily when there has been such a previous lesion; but that in many instances there is no previous lesion whatever. The conditions on which tuberculous infection in any given case appeared

to depend were, first, the number of the germs, and, second, the condition of the germs. Other things being equal, therefore, the larger the number of bacilli and the greater the activity of the virus, the stronger would be the chance of infection. Having referred to the question of the channel of infection, he said, in summing up, that the only factor necessary for the production of pulmonary phthisis was the bacillus tuberculosis or its spores.

One of the most positive and terse communications of the evening was the paper of Dr. J. West Roosevelt, on *The Relation of the Tubercle Bacillus to the Early Diagnosis and Prognosis of Phthisis*. In opening he spoke of the difficulties in the way of diagnosis which many cases presented, the responsibility of the physician, and the irreparable injury which might be done to a young man's prospects in life by the enunciation of a wrong opinion. If the bacillus were found in the sputum, all doubts would, of course, be removed. But suppose we do not find the bacillus, he went on to say, can we assert that phthisis does not exist? Decidedly not. It must be remembered that in phthisis we often have no tubercle which is so situated as to be connected with the air-passages, and it is quite possible for extensive tuberculous deposit to occur, and yet no bacilli be discharged. It is also possible for so much bronchial discharge to exist that the bacillus may be overlooked in the large quantity of expectoration. No one would, therefore, deny the existence of phthisis because the bacillus could not be found. Even though very many careful examinations be made and no bacilli be discovered, this evidence against the diagnosis of phthisis is slight; though, of course, the presence of bacilli would render such a diagnosis positive.

As seen in New York, he said, there were a number of cases of phthisis in which the lesion, until near the end, seemed to consist of the deposit of tubercles beginning in the upper lobes and gradually spreading and involving the lower. There were also some pleurisy and some bronchitis. Now, in these cases there was not much tendency for the tubercles to break down early in the disease. There being practically no pulmonary consolidation (nothing at first but a few scattered tubercular nodules), the physical signs were of little value. It was possible for this form of phthisis to progress very far and yet give no distinctive signs. Unfortunately, for the reason that scattered tubercles constituted the lesion and that these did not break down early and empty their bacilli into the bronchial secretion, the detection of the bacilli was frequently impossible at the very time when this would be of most value.

In another form of phthisis, together with the tubercle deposit, we had pneumonia, coagulation necrosis, marked bronchitis, etc., and practically this form, owing to the pulmonary consolidation,

gave signs earlier than the others. It also broke down over a greater extent of the lungs, and bacilli were frequently and abundantly discharged. It might be said that those cases presenting the greatest difficulties for diagnosis, not regarding the bacillus, presented also the greatest difficulties in finding the bacillus. In many of them it was not to be found at all, and the diagnosis had to be made from the physical signs.

As to the prognostic value of the bacillus, he thought it could hardly be said to have any. Patients going rapidly down hill would be found whose expectoration contained but few bacilli, and, on the other hand, large numbers of these might be found in the sputum of those whose disease was advancing but slowly, if at all. It was simply a question of the freedom with which cheesy matter was emptied into the bronchi. Strangely enough, there was a decided tendency for many to regard the bacilli discharged as a measure of the disease; as if they, and not the bacilli growing in the patient, did the harm. Hence we read of "diminution in the number of the bacilli" under varied treatments as a symptom of improvement. It might or might not be such a symptom. At best it was a most delusive one.

Watching for it, and laying stress upon it, he believed had done one great harm. It had given a longer life to the various so-called antiseptic methods of treatment; the word antiseptic being, here used, of course, as meaning destruction to bacillary life. "A strong solution of carbolic acid kills bacilli after some hours; therefore give very small doses of that agent (doses so small as to be, when diluted with a bulk of fluid equal to that of the blood, entirely harmless to the microbes), and thus cure phthisis." This was the real basis of reasoning for all such treatment; and how often had we heard in regard to each of the new antiseptic methods that "the cough, expectorations, and night-sweats improved, and the bacilli were reduced in numbers." To this should usually be added: "The patient died." Now the fact that the bacilli vary greatly in numbers from time to time had added somewhat to the apparent value of many different kinds of treatment. The time has come, he thought, for a protest to be made against the administration of poisons to unfortunate people in the so-called antiseptic treatment of phthisis. To do this, and to call the methods by which the particular poisons had so far been chosen, "scientific," was possibly to injure the patient, but certainly to exhibit a peculiar idea of what constitutes science. He explained that he would not for a moment be understood as objecting to the trial of any non-injurious treatment for phthisis; but he certainly did wish to protest against the giving of antiseptics tested as now, and calling it rational. While the complex body-cells were easier to kill than the more sim-

ply constructed bacilli, it did not seem very encouraging to try to kill the latter and yet leave the former untouched. It was probable that nourishing the phagocytes was better than trying to kill the bacilli. It was possible that empirically something may be found capable of acting as a specific bacillary poison, but no evidence had yet presented that such a substance exists, nor was it likely to be obtained by the present crude methods.

Dr. Roosevelt's conclusions were as follows:

1. The bacillus tuberculosis is of great positive value, but no negative value, in diagnosis.
2. In prognosis the bacillus is of but little value.
3. In both diagnosis and prognosis quite as much depends upon the careful study of the case as a whole as if there were no bacilli concerned in the production of the disease, except that a diagnosis is sometimes rendered positive, which would otherwise be doubtful, by finding the bacillus.

Prof. James Tyson, of the University of Pennsylvania, who had been invited to take part in the discussion, dwelt for some time on the difficulties which had attended the indisputable establishment of the proposition that the bacillus is the essential and only cause of tuberculosis. He then went on to say that attention could now be directed most profitably to the corollaries which grew out of this causal relation, and that the first evident deduction was that tuberculosis must be contagious. The contagiousness was so comparatively slight, however, that some explanation seemed necessary, and this explanation, he thought, would be found in the mode of dissemination, as shown by some recent observations of Cornet. This observer inoculated animals with sponge-scrapings from the walls of rooms occupied by phthisical patients. Large numbers of animals thus inoculated were found to be tuberculous, while the control experiments, made with sponge-scrapings from houses not inhabited by tuberculous patients, gave negative results. In no case was the dust of the walls infectious where sputum-cups were exclusively used to receive the expectorated matter, although such sputum abounded in bacilli. We thus learned that it is through the dried sputum whose bacillus-containing particles are disseminated in the air that the disease is spread; as was, indeed, originally suggested by Koch. Tuberculosis might be characterized as feebly or slightly contagious in the same way and for the same reason that typhoid fever was slightly contagious; because ordinarily the excreta are promptly removed, even if not disinfected, and it is only when they dry upon the linen, and thence become scattered through the air, that they enter the lungs or alimentary canal.

The same conditions also which intensified the contagion of the diseases long acknowledged to be contagious increased the operation of that of

phthisis. Thus, for instance, the disease was most frequent where people were crowded together, as in prisons, etc. Married people infected each other, and the members of healthy families might become infected one after another after removal to a house previously occupied by a tuberculous patient. In the same direction he pointed out some most valuable and laborious observations by Dr. Lawrence L. Flick, of Philadelphia, illustrated by a series of maps locating every death from tuberculosis in a single ward for twenty-five years, in which he showed that of the infected houses scarcely 10 per cent. are isolated—that is, have not an infected house next to them. About 23 per cent. of the infected houses, moreover, had had more than one case. Finally, through diagrams showing the distribution of small-pox, typhoid fever, diphtheria and scarlet fever, he showed that the groupings of phthisis are identical with those of contagious diseases.

In referring to the subject of the communication of tuberculosis through the alimentary canal he stated that while the general expression of the Paris Congress for the Study of Tuberculosis, held in 1888, was against the use of tubercular flesh, and especially tubercular milk, no absolute demonstration of the harmful effects of meat from tuberculous cattle seems to have been presented. Cagny, however, related a case in which tuberculous disease was caused in chickens by eating the sputa of a phthisical patient. In like manner, Mosler had reported the case of a patient who swallowed his own sputum in large quantities. Ten days after his first attack of cough diarrhoea and colic set in, and ten days later he died. The autopsy revealed tuberculosis of the lungs and intestine, but nowhere else in the body; and hence Mosler was inclined to refer tuberculosis of the intestine to swallowed sputum rather than to general infection, although he failed to produce intestinal tuberculosis in animals by feeding them with tuberculous sputum and lung tubercle.

Having referred to the possible transmission of tuberculosis by flies, as indicated by the observations of Spellman, Haushalter, and E. H. Hoffman, Dr. Tyson went on to say that the relation of the bacillus to heredity had as yet failed of a satisfactory explanation, and more particularly as regards congenital tuberculosis. The most probable explanation of the latter, he thought, was that it is passed from the blood of the mother to that of the fœtus through the placenta. Such transfer, however, presupposed, of course, the presence of bacilli in the blood of the mother; and while Weichselbaum had succeeded in demonstrating tubercle bacilli in the blood, it had been very frequent. It had to be admitted, too, that although Landouzy and Martin have obtained positive results after the inoculation of animals with the placenta of phthisical patients, no tubercle bacilli were found in the products;

which might therefore have been pseudo-tuberculosis.

Another important corollary, he said, related to the tenacity of the life of the bacillus. Cadere and Mallet found that tuberculous matter, when dried and pulverized, is capable of transmitting tuberculosis 102 days after such preparation; but they concluded that virulence does not persist after from 30 to 70 days, unless special care is taken to preserve it. Schule and Fisher claimed that tuberculous matter may remain active at least six months, while Pietro asserted that well dried sputum may retain infectious properties for nine or ten months at a mean temperature of 77° F.

Dr. H. M. Biggs, of the Carnegie Laboratory, presented the specific nature of phthisis in a very clear and forcible manner. No fact in medicine, with the possible exception of the essential cause of anthrax, he said, was better established than the causal relation of the bacillus of Koch to tuberculosis. The evidence, he believed, answered very nearly indeed to the exactness of mathematical demonstration, and it seemed to him that the profession could not too soon do away with the notion, held by many even yet, that heredity and other causes were prime factors in the etiology of phthisis. There was one, and only one cause, and that was the tubercle bacillus. That these other factors had an influence no one could deny, but the effect of the was simply to reduce the normal power of resistance in the tissues. In order that infection should result it was necessary that a dose of bacilli should be taken into the system and that these should have the effect of overcoming the tissue resistance. Depressed vitality from any cause and antecedent pathological processes existing in the lungs would naturally facilitate this action of the bacilli.

He considered that the tubercle bacilli are capable of causing the disease without the assistance of any other factor, provided that a sufficiently large number of them are admitted to the system. Heredity meant, then, he said, not the transmission of a predisposition to tuberculosis, but that tuberculous parents transmit to their offspring organs which are easily acted on by such agents as the tubercle bacillus; in other words, organs which have a less resisting power than those of robust individuals. In such organs there was simply an absence of strength, and not the positive possession of unfavorable qualities. If these points were accepted, he said it followed, first, that phthisis pulmonalis is distinctly contagious; and secondly, that it is a distinctly preventable disease.

The great question that lay before us, therefore, was the prevention of tuberculosis, and he thought that, in trying to solve this problem, we could not too strongly insist upon the origin of the disease from a single cause. In the work of prevention all discharges from tuberculous patients should be

disinfected, and all tuberculous animals should be destroyed; and we could only hope to carry out such a work by educating the profession and the public in this belief that the disease is due to a single cause. Whenever tuberculosis occurred in animal or man, the fact ought to be distinctly recognized that it was invariably the result of tubercular disease existing in some antecedent case.

Dr. H. P. Loomis followed Dr. Biggs, and in the course of his remarks he stated that he had found that in no less than 60 per cent. of all patients dying at Bellevue Hospital there were old tubercular changes in the lungs; the disease having been recovered from. After the meeting one of the physicians present remarked that if this statement were true it would be a great deal better if those suffering from tuberculosis should pay no attention to the disease and not seek medical advice, since statistics showed that of all tuberculous patients who came under treatment only 10 per cent. recovered.

Dr. Trudeau, of Saranac Lake, in the Adirondack Mountains, who exhibited some interesting specimens, stated that he had found it possible to produce in animals any kind of phthisis that was known in the human subject by properly regulating, first, the quantity of virus employed; second, the site of inoculation; and third, the environment of the animal. Acute miliary tuberculosis, for instance, could be caused by inoculating the vein of the ear. The animal would die of the infectious disease in about twenty-five days, and an examination would show the presence of tubercles everywhere in the body. By injecting the virus into the apex of the lung, a condition would be produced in which fibrous tissue would be found to predominate over the tubercular.

Dr. W. H. Thomson read a paper on *The Influence of the Microbe Theory on the Treatment of Phthisis*, in which he said that he had never expected any specific treatment to be of permanent value in phthisis on account of the organic nature of the tubercle bacillus. As illustrating this, he said he had never seen a case of small-pox, measles, or other specific disease that was shortened a single day by the administration of an antiseptic or any other agent whatever. He did not know of anything that the farmer could use that would kill the weeds, but not the potatoes, in his field; and in like manner we could not expect to find any agent that would kill the tubercle bacillus in the body, and yet not do injury.

But, at the same time, he thought that Koch's great discovery would not be barren of practical results. Having spoken of the apparent interdependence of bacterial growths upon each other, he referred to the wide prevalence of the streptococcus pyogenes, and said that it had seemed to him that this organism might perhaps pave the way, as it were, for the tubercle bacillus, which without its aid possibly would not find a suitable soil

for its development. If this were so, he thought it was of the greatest importance, first, to check all suppurative processes in the lungs; second, to remove the pus; and third, to prevent putrefaction of pus. One of the best agents against supuration was creosote, and it might be employed both internally and by inhalation. He related two cases of phthisis with well-marked cavities in which permanent recovery followed the use of creosote, and said that while he had, of course, met with many cases in which this remedy did no good, he believed that, on the whole, it was of more efficacy than any other. One important indication was to cause, as far as possible, a limitation of the tuberculous process by promoting the power of resistance in the tissues.

Dr. B. F. Westbrook, of Brooklyn, thought that as a rule a skillful examiner could make the diagnosis of phthisis in any case where the microscopist could do so by means of the sputum. In cases of pleurisy at the apex of the lung, however, where it was not known whether tuberculosis originally existed or not, he believed the examination of the sputum would often prove of diagnostic value. A few cases were also met with in which patients with weak chests have some crackling at the apex which may be due either to tuberculosis trouble or to emphysema; and here, too, he thought the presence or absence of the bacilli might be of considerable value. As to the matter of prognosis, if in any case repeated examinations failed to reveal the presence of bacilli in the sputum, he said he would conclude that there was no tuberculosis present, and that the trouble was probably due to chronic interstitial pneumonia. The mere numerical quantity of bacilli found in any case was, in his opinion, of no value.

As regards the matter of treatment, he believed that the only influence which the discovery of Koch had thus far had upon this was pernicious, since it had resulted in the introduction of all sorts of mischievous methods. There could be no specific treatment unless we could discover a specific antidote. Antiseptic agents, however, might be of great service in the treatment of fetid bronchitis, in cleansing and disinfecting cavities and the bronchial tubes, and in fortifying the constitution of the patient.

Dr. F. P. Kinnicutt, who closed the discussion, said that some of the antiseptic remedies had an undoubted value in removing foci of irritation and rendering the tissue in a measure aseptic. They arrested fermentation and had a stimulating effect upon the vital processes; and it was no doubt to such effects that the benefit observed from the use of creosote was due.

In the recent centennial celebration in this city the New York County Medical Association was officially represented by its president, Dr. Charles S. Wood, who acted as one of the aids to Gen.

Daniel Butterfield, chief marshal of the great civic parade on May 1. When the head of the procession reached Madison Square it was halted, and the chosen representatives of about a hundred societies of various kinds, of which the Association was one, marched from their rendezvous near by and preceded the column in passing President Harrison. On arriving in front of the reviewing stand they were drawn up in line before it, and Mayor Grant presented to the President in the name and behalf of the civic, industrial, benevolent and educational organizations there represented, an address engraved upon parchment and inclosed in a beautiful silver box. Upon the address was inscribed the date of the organization and incorporation, the purposes and the signature of the president of each society. The delegates then passed to seats especially reserved for them on the grand stand, south of the President, and assisted in reviewing the parade. The Executive committee of the County Association has ordered that the handsome insignia worn by Dr. Wood on this occasion shall be framed and carefully preserved as a memorial of its participation in the centennial celebration.

BOOK REVIEWS.

MEDICAL AND SURGICAL MONOGRAPHS. May Number. New York: Wm. Wood & Co.

There is published in the May number two monographs: The first upon "The Preventive Treatment of Calculous Disease and the Use of Solvent Remedies," by Sir Henry Thompson, F.R.C.S., M.B. The author states that we have the power to check the production of calculous matter at almost any stage of the complaint, and can almost certainly render its formation impossible if proper treatment be adopted. The dietetic treatment, upon which success largely depends, and the value of mineral waters are then fully discussed. The best, however, that modern science has done toward the solution of uric acid concretions, which are the basis of more than 90 per cent. of all calculi, is founded upon the use of potassium carbonate and the author unites with Sir William Roberts in agreeing that this is the most powerful solvent known, much better than either salts of sodium or lithium. Finally, it is necessary to admit that no evidence has yet been produced that the complete solution of a stone in the bladder has been effected by any alkaline agent whatever. The probabilities are in favor of the solution of small stones, but if large their solution is quite impossible.

The remainder of the volume, in fact, its greater portion, is devoted to "Sprains and their Consequences," by C. W. Mansell Moullin, M.A.,

M.D., F.R.C.S. The subject is very fully dealt with in some sixteen chapters, and the treatment is given in elaborate detail. The importance of the subject and the able treatment it has received in the hands of the author serve to recommend it.

THE INSANE IN FOREIGN COUNTRIES. By WILLIAM P. LETCHWORTH, President of the New York State Board of Charities. New York and London: G. P. Putnam's Sons. 1889.

This is a large octavo volume of 374 pages, containing numerous and valuable illustrations. The author spent seven months in diligent personal examination of the various kinds of provision made for the insane poor in England, Scotland, Ireland, Sweden, Denmark, France, Germany and other Continental countries, and has given the results of his investigations in this volume, preceded by a very interesting retrospective introductory chapter. Every person interested in the welfare of the insane poor, and the provisions made for their protection and support in different countries, will find this a most interesting and valuable volume; and equally so whether such person be a physician or not.

MISCELLANY.

SCIENTIFIC USES OF THE EIFFEL TOWER.—M. Janssen, of the Institute of France, is of opinion that the Eiffel Tower will have many scientific uses. One of the greatest difficulties of meteorological observations is the disturbing influences of the station of observation itself. How, for example, can a true deviation of the wind be observed if a purely local obstacle causes it to deviate? And how can a true temperature of the air be determined by a thermometer influenced by radiation from surrounding objects? Thus, the meteorological elements of great centers of habitation have to be taken outside those centers, and at a certain height above the soil. The Tower, since it rises to a great height, and from the nature of its construction does not modify in any way the meteorological elements to be observed, will get over this difficulty. A height of 300 yards is in itself not negligible quantity from the point of view of rainfall, temperature, and pressure, but these circumstances give all the more interest to the institution of comparative experiments on variations due to altitude; the electrical interchanges between the soil and the atmosphere can also be studied to advantage. Special arrangements can be made for avoiding accidents, and results of great interest should be obtained. M. Janssen recommends also the institution of a service of meteorological photography. A good series of photographs would give forms, movements, modifications which the clouds and atmospheric conditions undergo from sunrise to sunset. Thus a history of the skies would be written on a radius not hitherto dealt with. In physical astronomy various other observations might be taken, especially in relation to the study of telluric spectrum. M. Eiffel announces that three laboratories have already been arranged on the Tower. One will be devoted to astronomy, and the second will contain registering apparatus from the central bureau of meteorology, and will be devoted to physics and meteorology. MM. Mascart and Cornu expect to draw great advantages from its use in the study of the atmosphere. The second is

reserved for biology and micrographic study of the air, to be organized by M. Henocque. M. Cailletet is arranging a great mercurial monometer, with which he expects to obtain pressure as high as 400 atmospheres.—*British Medical Journal*.

MCLEAN COUNTY MEDICAL SOCIETY.—The regular monthly meeting of the McLean County Medical Society was held at the office of Drs. Darragh & Corley, on Monday, May 6th, at 2:30 P.M. There were present, Drs. Rhoda Galloway, C. F. Vandervoort, M. D. Hull, E. P. G. Holderness, N. F. Jordan, J. L. White, Wm. Hill, A. T. Darragh, H. Parkhurst, C. J. Corley, Secretary, G. M. Smith, S. T. Anderson, F. J. Parkhurst, C. Reedy, E. Mammen, F. J. Welch and L. A. Burr.

Dr. J. L. White, one of the Committee who went to Springfield in the interest of the Medical Practice Act, stated that in his opinion the majority of the Legislature were in favor of the above Act, and, furthermore, there was not the least danger of the section being stricken out.

Dr. Darragh reported a case of a young lady attending school in Indiana who had malignant scarlatina and when she was convalescing wrote home, and in a few days after some of the family were stricken with the above disease, supposed to have been produced by the letter paper. The following were appointed delegates to the State Medical Society meeting at Jacksonville, Ill.: Drs. F. J. Parkhurst and E. Mammen. To the American Medical Association meeting at Newport, R. I., Drs. Hull and Covey. Dr. Anderson then read an essay on "The Quinine Hobby." It was a witty and interesting one and received an attentive listening from all present.

LETTERS RECEIVED.

Dr. J. H. Etheridge, Chicago; Dr. John Barney, Dunkirk, N. Y.; Dr. C. M. Daniels, Buffalo, N. Y.; C. C. Purington, Boone, Ia.; Dr. J. S. Dorsey-Cullen, Richmond, Va.; Dr. W. H. Dunlop, Syracuse, N. Y.; W. F. Snorgrass, Excelsior, Mo.; J. A. T. Bernays, Minneapolis, Minn.; Dr. A. F. A. King, Washington; J. H. Bates, New York; Dr. Stanford E. Chaillé, New Orleans, La.; A. E. Walesby, Louisville, Ky.; Dauchy & Co., New York; W. P. Cleary, New York; I. Haldenstein, New York; Dr. J. H. Eldredge, East Greenwich, R. I.; Dr. W. D. De Long, Pikesville, Pa.; Dr. C. C. Fite, Knoxville, Tenn.; Dr. J. M. Dunham, Columbus, O.; Dr. Arthur J. Hall, Washington; Dr. J. V. Schofield, Harris City, Ind.; Dr. C. H. Franklin, Union Springs, Ala.; Dr. R. A. Kinloch, Charleston, S. C.; B. Pulskamp, Washington; Dr. T. E. Potter, St. Joseph, Mo.; M. Brewer, Monmouth, Ill.; Dr. J. G. Weaver, Strasburg, Pa.; Lea Bros. & Co., Philadelphia; T. A. McKinnill, Washington; Dr. F. Dowling, Cincinnati; Dr. E. P. Sale, Memphis, Tenn.; Nugent, Brown & Co., Fargo, Dak.; Dr. Willis G. Tucker, Albany, N. Y.; Dr. C. P. Thayer, Boston, Mass.; Dr. C. Thompson, New York; Dr. K. von Ruck, Asheville, N. C.; Dr. A. L. Hummel, Philadelphia; Dr. Geo. F. Cook, Oxford, O.; Dr. Samuel N. Nelson, Boston; Canton Surgical and Dental Chair Co., Canton, O.; Emma B. Orcutt, Hardwick, Mass.; Dr. E. J. Sherron, Sing Sing, N. Y.; Dr. C. E. McClary, Syracuse, N. Y.; Dr. Frank Billings, Chicago; Dr. C. Brown, Adrian, Ill.; Dr. W. H. Forbes, Richmond Hill, N. Y.; Dr. Wm. E. Quine, Dr. Chas. T. Parkes, Dr. W. E. Casselberry, Chicago; Dr. Robt. T. Edes, Washington; Dr. Joseph Eastman, Indianapolis; J. T. Petty, Washington; Dr. J. S. Riggs, Redland, Cal.; Dr. W. Franklin Coleman, Chicago.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from May 1, 1889, to May 10, 1889.

By direction of the acting Secretary of War, Capt. F. C.

Ainsworth, Asst. Surgeon U. S. Army, will proceed to Albany, N. Y., on business connected with the Medical Department. Par. 7, S. O. 105, A. G. O., May 7, 1889.

Capt. Walter W. R. Fisher, Asst. Surgeon U. S. Army, is hereby granted leave of absence for one month. Par. 1, S. O. 30, Hdqrs. Dept. of California, San Francisco, Cal., April 21, 1889.

Capt. D. M. Appel, Asst. Surgeon, relieved from duty at Fort Sill, Ind. Ter., and ordered to Ft. Bliss, Tex.

Capt. S. G. Cowdrey, Asst. Surgeon, relieved from duty at Ft. Bliss, Tex., and ordered to Ft. Marcy, N. M.

Capt. Jas. A. Finley, Asst. Surgeon, relieved from duty at Ft. Assiniboine, M. T., and ordered to Ft. Totten, Dak.

Capt. Aug. A. DeLoffre, Asst. Surgeon, relieved from duty at Ft. Totten, Dak., and ordered to Columbus Bks., O.

Capt. B. D. Taylor, Asst. Surgeon, relieved from duty at Columbus Bks., O., and ordered to Ft. Sill, I. T. Par. 25, S. O. 104, A. G. O., Washington, May 6, 1889.

By direction of the acting Secretary of War, First Lieut. William P. Kendall, Asst. Surgeon, will be relieved from duty in the Dept. of California, after he shall have complied with the requirements of par. 2, S. O. 29, A. G. O., April 24, 1889, from these headquarters, and will then proceed to Ft. D. A. Russell, Wyo., for duty at that station. Par. 28, S. O. 104, A. G. O., May 6, 1889.

By direction of the Secretary of War, Capt. Paul R. Brown, Asst. Surgeon, is relieved from further duty in the Dept. of the Platte, and will proceed to Ft. Thomas, Ariz., and report in person to the commanding officer of that post for duty, and by letter to the commanding officer Dept. of Ariz. Par. 10, S. O. 105, A. G. O., May 7, 1889.

Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending May 11, 1889.

Medical Inspector Grove S. Beardsley, detached from the "Brooklyn," proceed home and wait orders.

P. A. Surgeon P. A. Lovering, detached from the "Brooklyn," proceed home and wait orders.

Asst. Surgeon Oliver D. Norton, detached from the "Brooklyn," proceed home and wait orders.

Surgeon J. A. Hawke, detached from the "Essex," proceed home and wait orders.

Asst. Surgeon C. F. Stokes, detached from the "Minnesota" and to the "Iroquois."

Surgeon John F. Bransford, orders to the "Iroquois" revoked, resignation accepted, to take effect May 4, 1890, with leave of absence granted to that date, with permission to leave the United States.

LECTURES.

DUODENAL AND GASTRIC ULCERS.

A Clinical Lecture delivered at the Hospital of the University of Pennsylvania.

BY WILLIAM PEPPER, M.D., LL.D.,

PROVOST AND PROFESSOR OF THE THEORY AND PRACTICE OF
MEDICINE, UNIVERSITY OF PENNSYLVANIA.

I cannot altogether agree with those who think that, as regards the frequency of gastric ulcer, it is much more often suspected when it does not exist, than overlooked when actually present. But all are agreed as to the rarity of duodenal ulcers. Of this latter, it is doubtful if more than 70 authenticated cases are on record; while gastric ulcers, either cicatrized or open, are found in about 5 per cent. of persons dying from all causes. It may be very difficult to decide whether an ulcer which is believed to exist is gastric or duodenal in position. And this fact, coupled with the frequency of these ulcers, their dangerous character, and the great importance of proper treatment, leads me to report to you some recent cases.

It is true that you can diagnose gastric ulcer with confidence in cases attended with characteristic paroxysmal circumscribed epigastric pains extending through the back, coming on after eating, and disappearing only when the stomach is emptied by vomiting; with localized tenderness; with frequent vomiting, hyperacidity of the contents of the stomach, and with recurring hæmorrhages of bright blood in varying amount, with or without bloody discharges from the bowels. But it must be remembered that such ulcers may be latent and cause only slight, if any, symptoms until sudden and, as I have more than once seen, immediately fatal hæmorrhage, or else sudden perforation occurs. Or, indeed, the ulcer may be unexpectedly found at the autopsy of a case in which no significant symptoms had been present. Many cases are on record illustrating these statements. The same may be said of the duodenal ulcer; and I am reminded of the following case, which I saw but once, as it was sent to me, in 1881, by Dr. W. K. Hull, of Williamsport, for examination.

Case 1.—Duodenal Ulcer; Obscure Symptoms, Death from Perforation and General Peritonitis.

Mr. A. G., æt. 43, a dry-goods merchant of excellent personal habits, had for six years been complaining of occasional attacks of indigestion and pain (not of much severity) over the right side of the abdomen. His general health had not suffered much, though he had lost flesh moderately. His height was 5 ft. 9 in.; his weight 126 lbs.; he was of a light, spare build. He knew of no cause for his trouble, which I regarded as duodenal catarrh with hepatic congestion. He had never suffered a burn of any severity; nor any injury to that part of his body. He had been in the habit of eating rapidly without properly chewing the food. He took frequent Turkish baths, but only since the appearance of symptoms. He had never had jaundice. The urine was at times dark, but when I examined him it contained neither albumen nor sugar. There was no vomiting; no intestinal hæmorrhage; no local tenderness. The appetite was rather craving; the tongue but slightly coated; the bowels sluggish; the area of liver dulness slightly enlarged. The lungs and heart were normal; there was no marked atheroma of the superficial arteries.

I recommended the abandonment of Turkish baths; the constant use of a flannel belt around the body; a carefully restricted diet; and alternate courses of nitrate of silver and of iron, with belladonna and quinine.

I saw him on January 22. I heard from him in ten days that he was doing very well. On February 12, after a short and gentle ride on horseback, he was seized with atrocious pain in the upper part of the abdomen, followed by immediate collapse and rapidly fatal general peritonitis. The autopsy revealed an ulcer of the duodenum, which had perforated. It was seated on the anterior wall of the horizontal portion, about an inch from the pylorus. It was $\frac{3}{8}$ inch in diameter, with sharp punched-out edges. There was no ulcer in the stomach.

I fear that it must be admitted that in this case it was impossible to make a correct diagnosis, as all the symptoms seemed adequately explained by the duodenal catarrh.

The next two cases I shall report were attended, on the other hand, with marked and alarming symptoms. They are specially interesting from their severity; from some unusual features; from the illustration they afford of the differential diagnosis of gastric and duodenal ulcer; and from their termination in recovery.

Case 2.—Gastric Ulcer; Gastralgie Pains; frequent Vomiting; Hemorrhage; Septic Parotitis; Recovery after Desperate Illness.

Mrs. X., æt. 39, was seen in consultation with Dr. T. V. Crandall. She had been suffering for many months with uterine trouble, and had been subjected to an operation for laceration of the cervix, following which there was a prolonged state of poor nutrition and neurasthenia. Her vitality and circulation were greatly depressed. She then suffered for three months from severe paroxysms of pain of gastralgie character, recurring frequently and irregularly. There was no vomiting, but progressive decrease in power of taking and digesting food, with quite rapid loss of flesh and color. There was also tenderness over the stomach. At the close of this time vomiting began, and almost at once became very frequent and proved uncontrollable by ordinary remedies. I saw her at this time. She was immediately put to bed, upon an absolute milk diet, with repeated small blisters over the stomach, and with minute doses of nitrate of silver internally. Rectal enemas were used from the first. The vomiting was not, however, controlled either by the silver nitrate, or by any other remedy that was used; opium by the rectum was required to relieve pain and to secure rest, but it produced no good effect upon the vomiting. It was also necessary to use hypodermic injections of morphia and atropia quite frequently. The tongue became parched and brown and deeply fissured; the anæmia grew intense, and there was occasionally oozing of blood from the nose, and from the gums. Vomiting of small quantities of bright, fresh blood occurred repeatedly. At the close of ten days slight febrile action set up, the temperature rising to about 101° at night. She became so emaciated and exhausted, that it seemed that death was imminent. She was then attacked with parotitis, undoubtedly septic in character, first upon one side and then upon the other. Fortunately this ended in resolution. All internal medication was abandoned, and for many days no attempt was made to administer food by the month. She was anointed assiduously with sweet oil, and for four weeks was maintained exclusively by rectal enemas. Veratria ointment was used externally, in conjunction with morphia hypodermically, and opium by the rectum to control suffering. Despite her desperate condition she began to im-

prove; vomiting grew less frequent, and blood ceased to be ejected. The fever subsided. As resolution of the parotitis advanced, she became able to bear teaspoonful doses of skim milk. This was cautiously increased, and she was kept upon an absolute milk diet for about three months. She was then able to be lifted from bed, and moved carefully to the seashore. After seven weeks of illness, recovery was complete, but was marked by protracted and obstinate constipation with troublesome rectal fissure.

Case 3.—Ulcer, Probably Duodenal; Gastralgie Pains; Persistent Vomiting; Severe Repeated Hemorrhages altogether Intestinal; Circumscribed Tumor; Recovery after Desperate Illness.

Mrs. P., æt. 38. Was seen in consultation with Dr. H. A. M. Smith, of Gloucester City, N. J. She had enjoyed general good health, but during the autumn of 1888, had been overtaxed and worried greatly in connection with business affairs. She was attacked December 14, with severe gastralgie pain, which recurred regularly every afternoon at about the same hour. Vomiting began on December 29, and at once became frequent and was attended with marked exhaustion, so that she took to bed on January 1, 1889. In spite of various remedies and careful regulation of diet, the vomiting persisted. It presented itself rather as a frequent raising of small quantities of dark colored mucus, which at times had a purulent appearance. There were rapidly progressive emaciation, weakness and anæmia. On February 5 she had a large hæmorrhage from the intestine. The blood was dark, but not offensive. This caused extreme debility. Between that date and February 14, there was continued discharge of blood from the bowel, including six large hæmorrhages. There was not a single drop of blood vomited.

I saw her first on February 5. She was profoundly anæmic, and partially collapsed. During the ensuing ten days it seemed scarcely possible that she should survive. Examination showed tenderness to the right of the median line, and there was a distinct circumscribed induration below the lower edge of the right ribs, corresponding to the position of the duodenum. This could be outlined as a painful lump of about two inches in diameter. There was no jaundice at any time. She continued to raise frequently small amounts of dark mucus. There was no melæna after Feb. 14. Fortunately the rectum continued retentive, and the nutritious enemas were evidently absorbed. She remained in a desperate condition for nearly three weeks, and even then her improvement was so slight and gradual, that her recovery seemed doubtful for some time longer. The lump described above gradually decreased in

size, and now, May 1, is no longer perceptible. She continued to eject mucus in decreasing amounts until early in April, since when it has stopped entirely. The stomach rapidly regained its digestive power, and she is now able to eat quite freely and without any distress, meat, vegetables, bread and butter. All is well digested, and the bowels are moved daily with a healthy stool. As soon as she sat up, and her legs became pendent, she suffered very severely from numbness and anaesthesia, with a distressing sense of restlessness in them; there was no oedema. This has gradually disappeared under the use of veratria ointment with bandaging, and she is now able to walk about her room quite freely. In the treatment of this interesting case, rectal injections were used from February 1, until the last week in March. They occasioned no special inconvenience, and on no occasion did they induce an evacuation. For two weeks prior to the first hæmorrhage no nourishment whatever was retained. Reed and Carnrick's liquid peptonoids was then administered in small and frequently repeated doses. It proved acceptable and for some time was the chief reliance in feeding her, and she still continues its use. The rectal injections were given every four hours, and consisted of 8 ounces of peptonized milk, and of peptonized beef-tea alternately. Nitrate of silver was ordered on February 6, and its use was continued until 16 grains had been taken, grain $\frac{1}{4}$ t.d. being used. She then took oxalate of cerium grain $\frac{1}{2}$ four times a day for two weeks, and then resumed the nitrate of silver in small doses, $\frac{1}{16}$ t.d., which has been continued until the present date. Her complete recovery now seems assured.

It cannot be doubted that ulcer existed in each of these cases, as severe recurring pain, tenderness, vomiting, and finally hæmorrhage, were present. The interesting question arises whether, in Case 3, the position of the ulcer was gastric or duodenal. It is evident that we cannot place much reliance upon the location or character of the pains. In some cases of gastric ulcer there is severe paroxysmal pain strictly localized in a circumscribed spot in the epigastrium, coming on soon after eating, increased by pressure, and disappearing as soon as the stomach is relieved of its contents. But there are many cases, of which Cases 2 and 3 are good examples, where the paroxysms of pain assume the usual diffuse gastralgic type. It is comparatively rare that there exists such definite localized pain as will enable us to determine accurately the site of the ulcer. Nor can it be said, as will be shown in Case 4, below reported, that the character or frequency of the vomiting is conclusive. Vomiting may be absent from first to last, in either gastric or duodenal ulcer. This is, to be sure, rare. It is the

rule more constantly in gastric than in duodenal ulcer that vomiting occurs repeatedly and soon after the ingestion of food. The argument is vitiated by the impossibility of determining the amount of coexistent gastric catarrh. In all the above cases this was present in marked degree; and especially in Case 3 did the character of the ejecta indicate that the vomiting was chiefly due to catarrh of the mucous membrane.

Not even when hæmorrhage occurs can we always decide. Still, it is a general rule that, in gastric ulcer, some of the effused blood—unless it escapes very slowly and all passes into the intestine, is vomited; and that on the other hand, in duodenal ulcer, unless the blood escapes very rapidly, so as to overcome the pyloric resistance, or unless the ulcer is seated very close to the pylorus and is accompanied with pyloric incompetence, the blood is discharged by stool. Case 4 will illustrate the latter statement; and Case 3, judged by this rule, would seem to be also one of duodenal ulcer. There are too many exceptions to permit a dogmatic assertion; yet here this view is confirmed by the existence of a small but distinct tumor in the duodenal region. It is important to remark that, though not a common symptom, tumor may be present in simple ulcer, either gastric or duodenal, and more frequently in the latter. The tumor is due to peritoneal exudation and adhesions, associated, in old cases, with thickening of all the tissues involved.

Even when no thickening or swelling can be detected by palpation, it is common enough to find a circumscribed spot of tenderness on pressure, which may be attributed to the sensitive state of the peritoneum outside the base of the ulcer, and which therefore may serve, when present, as a guide to the position of the ulcer. Great care is required to avoid being misled by mere epigastric hyperæsthesia, which is so common; and by tenderness of the nerve points in the abdominal walls. The position of the small tender swelling in Case 3 indicated that it was due to local peritonitis about the first portion of the duodenum; and the lesions in Case 4 showed clearly that there probably had been a distinct sense of resistance and thickening, if not of actual tumor, in the same region. Upon the whole the evidence seems to indicate that the ulcer in Case 3 was in the duodenum. There had been no severe pain—but this is merely of negative value; though it is far more usual to have recurring spells of varying intensity, as in Cases 1 and 4. There had been no jaundice, which occurs, as would be expected, in some cases of duodenal ulcer, from occlusion of the bile duct from extension of catarrh, or from thickening of the duodenal tissues. But this symptom is often absent, as in Cases 1 and 4. It should be noted also that the restoration of the tone and activity of the stomach was, in Case 3, more prompt and complete than is

seen ordinarily in cases of gastric ulcer ending in recovery. Before leaving these cases, the fever in Case 2 should be carefully noted. Simple ulcer of the stomach or duodenum is not often attended with fever. Still, this may develop from the occurrence of local peritonitis; or it may be septic, as it apparently was in this case. The complicating parotitis confirms this. The fever which occurred during the last few days of life in Case 4 was too brief and depended upon too many factors to have any special significance. The case is, however, full of clinical and pathological interest.

Case 4.¹—Duodenal Ulcer; Gastric Catarrh of long Standing; Persistent Vomiting; Gastralgic Pains; Repeated Copious Discharges of blood by Mouth and Rectum, followed by Death from Sepsis and Exhaustion.

I was called to see Mr. F. on the morning of Saturday, March 2, immediately after an enormous hæmorrhage from the stomach, which had been followed by almost fatal collapse. He was 32 years old, and a man of fine physique, who had formerly for many years indulged excessively in athletic sports. It was believed by many that he had often overtaxed himself. He had also been careless in his habits of living, especially in regard to his meals, which were irregular, and eaten hastily. He had used wine freely. He had never met with any serious accident, nor received any severe burn. For fully five years he had suffered with violent gastralgic attacks, recurring frequently and irregularly. The pain was referred to the epigastrium; not rarely pressure seemed to afford relief. His spells of pain were not brought on directly by food; and he had learnt by experience that the rapid drinking of large quantities of cold milk would afford temporary relief. It was clear that gastric catarrh had long existed. Vomiting became a symptom three or four years ago, and had continued quite frequent. It would usually occur in the morning, when he would bring up without much effort considerable amounts of mucus and acid liquid. During the day, however, he would not infrequently raise small quantities of liquid, so acid that it would bite the mouth. There had never been any jaundice. Local tenderness was not complained of, but there was distressing abdominal distension. He had been under the treatment of several physicians, but had derived no special advantage from any remedies. Most relief was obtained from restricted diet largely composed of milk. Noting this, he had continued to use milk in large quantities, especially as excessive thirst was another prominent and distressing symptom in the case. He also ate a considerable amount of solid food, while at

the same time he drank as much as eight quarts of milk in twenty-four hours, taking it for the most part very cold, and in very large draughts. At times his thirst was so intense that he would raise the pitcher to his lips and drink as much as a quart at a single pull. He lost flesh moderately; had a bad color; and began to tire more readily. There had never been any blood vomited until the sudden large hæmorrhage above mentioned. He was at his office desk when this occurred, and fell upon the floor in syncope from the shock. The amount of blood which escaped cannot be estimated accurately, but an experienced physician who saw him immediately afterward says it was certainly over a quart. I saw him for the first time two hours after the hæmorrhage. He was deathly pale, with a miserably small and running pulse; and was complaining bitterly of intense thirst. There was no vomiting; the bowels had not been moved; the belly was moderately distended. He had taken a large dose of Monsell's solution. Nutritious and stimulating enemata were given. Digitalis was injected under the skin; smaller doses of the astringent were continued internally. He reacted gradually through the day, and by night seemed much better; but early on Sunday morning became restless and distressed, and soon had another enormous discharge of blood from the stomach. This again was certainly over a quart, and was soon followed by a large discharge of black tarry blood from the bowel. Alarming collapse again ensued. Monsell's solution was repeated; a bag filled with cracked ice was bound tightly upon the epigastrium; hypodermics of ether and digitalis were administered. He reacted imperfectly toward evening. No further hæmorrhage occurred. But during Monday he sank in spite of all efforts, and at 1 o'clock Tuesday morning, in consultation with Dr. J. William White and Dr. Judson Daland (whom I had placed in constant attendance upon the case), it was decided to transfuse. Dr. White injected into the left median basilic vein 32 oz. of hot saline solution, composed of sodium chloride 5ij; potassium chloride gr. xij; sodium phosphate gr. vi; sodium carbonate ʒij; alcohol ʒss; distilled water, q. s. ad Oij. The temperature of the liquid injected was 110° F.

The patient's condition was desperate when the injection was given. So exsanguine was he that when the vein was opened, it lay collapsed on the grooved director with not even an oozing of blood. Within a few minutes after the injection, blood began to flow from the distal part of the vein and it soon became necessary to ligate it. Its immediate effects were gratifying, and were especially marked upon the pulse, which became slower, stronger and fuller. His thirst was constant and intense. The transfusion did not help it. The good influence of the trans-

¹ This is the same case which was reported partially in the Medical and Surgical Reporter for April 20, 1889.

fusion did not last many hours, and, in fact, its effect was so transient that at no time until the occurrence of death upon the following Saturday, March 9, did we feel encouraged to repeat it. The stomach continued retentive. The patient's demands for liquids were incessant and imperative. They were resisted with difficulty, and only small quantities of milk and lime water and of a mixture of one part of champagne with two of Apollinaris water (kept frozen in an ice-cream freezer), were given alternately. Rectal enemas of peptonized liquids were given at intervals of four hours. The rectum proved unusually tolerant. It appeared probable that all the enemas were absorbed, although from time to time large quantities of horribly offensive decomposing blood were discharged from the upper bowel. Listerine was added to the enemas as a disinfectant. The medication was exclusively by hypodermic injection. Morphia, atropia, digitalis and ether were used with great discretion and with excellent result by Dr. Daland, according to the indications from hour to hour. On Wednesday, March 6, the temperature began to rise, and on Thursday and Friday it ranged from $101^{\circ}.5$ to $102^{\circ}.5$. It sank again on Saturday prior to death. No local cause for the fever could be determined; it seemed chiefly septic, though intestinal irritation played a part. The pulse continued extremely small and weak, and rapid.

Auscultation showed a distinct systolic murmur, heard over the sternum. This was regarded as at least in part organic, and due to disease of the aortic valves. The urine was examined several times after Tuesday, the 5th. It contained a very small amount of albumen; no sugar. There were a few leucocytes, but not sufficient to account for the albumen. There were no tube casts or blood. Death occurred gradually from exhaustion and heart failure.

Autopsy showed moderate enlargement of the heart. There were short fibroid vegetations on the free surface of the aortic valves. No other cardiac changes were present. The lungs were normal. The diaphragm was unusually thick and powerful. The spleen and pancreas were normal. The kidneys were very large; there were two small retention cysts on the surface, but no serious organic change. The liver was enlarged, weighing $4\frac{1}{2}$ lbs. The gall bladder was distended with 5 ozs. of dark bile; the bile ducts were normal. The stomach was greatly dilated, its capacity being over 3 quarts; its walls were thickened, and the mucous membrane showed evidences of chronic catarrhal inflammation. No ulcer or cicatrices were found. The duodenum was tightly adherent by old and firm adhesions to the liver, the gall bladder, and adjoining parts. It was greatly distended and its walls were softened, so that they readily broke upon traction. Upon its anterior face, about $\frac{1}{2}$ inch from the py-

lorus, there was a large irregularly round ulcer, with a diameter of almost 2 inches. The tissue of the duodenal wall at this point was much thickened and fibroid. About the centre of the ulcer the pancreatico-duodenal artery was ulcerated through, each portion of the vessel containing a soft thrombus. The ulcer was shallow, with slightly terraced edges. At about the beginning of the ileum there was a small fibroid growth projecting into the bowel. The stomach and small intestines contained no blood, but, in spite of the frequent and large bloody discharges during five or six days, the colon still contained a large amount of black faecal matter and of decomposing blood. It is evident, therefore, that at the time of the discharge of blood by vomiting, there was also an enormous amount of blood which passed down into the bowel.
